Canadian content written by Cynthia Murray, BN, MN, PhD

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Discuss physiological and psychosocial health concerns during the transition of the child from intrauterine to extrauterine life.
- Describe characteristics of physical growth of the fetus and of the child from birth to adolescence.
- Describe cognitive and psychosocial development from birth to adolescence.
- Describe the interactions that occur between parent and child.
- Explain the role of play in the development of the child.
- Identify factors that contribute to self-esteem in youth.
- Describe the influence of the school environment on the development of the child.
- Plan culturally appropriate health promotion activities for children of all backgrounds.
- Discuss ways in which you can help parents meet their children's developmental needs.

Human growth and development are continuous, intricate, complex processes that are divided into stages organized by age groups. This arbitrary, chronological division is used because it coincides with the timing and sequence of maturational changes that allow children to progress through a series of developmental stages and associated tasks (Box 22-1). This chapter focuses on the various physical, psychosocial, and cognitive changes. It also focuses on health risks and concerns during the various stages of growth and development. Major developmental theories are discussed in Chapter 21.

► BOX 22-1 Developmental Age Periods

Prenatal Period: Conception to Birth

Germinal: Conception to approximately 2 weeks

Embryonic: 2 to 8 weeks

Fetal: 8 to 40 weeks (birth)

Because of rapid growth rate and total dependency, this is one of the most mutable and vulnerable periods in the developmental process. The relationship between maternal health and certain manifestations of normalities and abnormalities in the newborn emphasizes the importance of adequate prenatal care to the health and well-being of the infant.

Infancy Period: Birth to Approximately 12 to 18 Months

Neonatal: Birth to 28 days

Infancy: 1 to approximately 12 to 18 months

The infancy period is one of rapid motor, cognitive, and social development. Through bonding with the parent or other caregiver, the infant establishes a basic trust in the world and the foundation for future interpersonal relationships. The critical first month of life, termed the **neonatal period**, although part of infancy, is often differentiated from the remainder of infancy because it is characterized by major physical adjustments to extrauterine existence and by the psychosocial adjustment of the parents to their new roles.

Early Childhood: 1 to 6 Years

Toddler: 1 to 3 years

Preschooler: 3 to 6 years

This period, which extends from the time children begin walking until school entry, is characterized by intense activity and discovery. It is a time of marked physical and psychosocial development. Motor development advances steadily. Children at this age acquire language and wider social relationships, learn role standards, gain self-control and skill mastery, develop increasing awareness of dependence and independence, and begin to develop a self-concept.

Middle Childhood: 6 to 12 Years

Frequently referred to as the *school age*, this period of development is one in which children expand relationships outside the family group and activities revolve around peer relationships. Physical, cognitive, and psychosocial development advances steadily, with emphasis on developing skill competencies. Social cooperation and early moral development take on more importance, with relevance for later life stages. This is a critical period in the development of a self-concept.

Adolescence: 12 to Approximately 19 Years

The period of rapid maturation and change known as adolescence is considered to be a transitional period that begins at the onset of puberty and extends to the point of entry into the adult world—in Canada, usually high school graduation. Biological and psychological maturation are accompanied by physical changes and emotional turmoil, and the self-concept is redefined. In the late adolescent period, children begin to internalize all previously learned values and to focus on an individual, rather than a group, identity.

Adapted from Hockenberry, M. J., & Wilson, D. (2011). *Wong's nursing care of infants and children* (9th ed.). St Louis, MO: Mosby.

children's needs are assessed and met by the plan. In a developmental approach, organized care is directed at an individual child's current level of functioning to motivate self-direction and health promotion; for example, you might instruct parents to encourage toddlers to feed themselves in order to advance their developing independence and promote their sense of autonomy. Understanding an adolescent's need to be independent should prompt you to negotiate with the adolescent to establish a contract about the care plan and its implementation. All care must be planned so that it is culturally safe (see Chapter 9), ethical and legal (see Chapters 7 and 8), and informed by the best evidence available (see Chapter 6).

Conception

From the moment of conception, human growth proceeds at a predictable and rapid rate. During the prenatal period, the embryo grows from a single cell to a complex, physiological being. All major organ systems develop in utero, and most function before birth.

Intrauterine Life

Intrauterine life that reaches full term usually lasts approximately 9 calendar months, or 40 weeks. The length of pregnancy is computed according to **Nagele's rule**, in which you count back 3 months from the first day of the pregnant woman's last menstrual period and then add 7 days. **Fertilization** occurs when a sperm penetrates the ovum and the material from both cell nuclei unites. The newly formed organism, known as a **zygote**, has its full genetic complement (1 pair of sex chromosomes and 22 pairs of autosomal chromosomes). The ovum and the sperm each contribute one chromosome to each pair. Through this mechanism, genetically determined characteristics (such as eye colour) are transmitted from parent to child and genetic conditions (such as Down syndrome) can result.

The zygote moves through the fallopian tube to the uterus within 3 to 4 days. During this time, the zygote continues to divide. Within 3 days, a solid ball of cells, the **morula**, has formed. The morula continues to develop and forms a central cavity, or **blastocyst**. Even at this early stage of development, cells begin to differentiate in structure and function. Cells at one end of the blastocyst develop into the **embryo**, and those at the opposite end form the **placenta**. Between days 6 and 10, some of the cells secrete enzymes that allow the blastocyst to burrow into the endometrium and become completely covered; this process is known as **implantation**. Chorionic villi—fingerlike projections that emerge from the outer sac surrounding the embryo—obtain oxygen and nutrition from the maternal blood supply and dispose of carbon dioxide and waste products.

The placenta produces essential hormones that maintain the pregnancy. It also provides nutrients to the developing fetus and removes wastes. Because the placenta is porous, noxious materials such as viruses and drugs can pass from mother to child. The effect of noxious agents on the fetus depends on the developmental stage in which exposure takes place; the embryonic stage (2 to 8 weeks after conception) is critical because the organ systems and the main external features are developing. The period of gestation is divided equally into three periods called *trimesters*.

First Trimester. During the first trimester, the first 3 calendar months, fetal cells continue to differentiate and develop into essential organ systems. As cellular change

Selecting a Developmental Framework for Nursing

Providing developmentally appropriate nursing care is easier when the care plan is based on a theoretical framework (see Chapter 21). An organized, systematic approach ensures that

(differentiation) and rapid organ growth (organogenesis) occur, each organ is vulnerable to conditions in the environment. Interference with growth can cause the congenital absence of an organ system or extensive structural or functional alterations. Because several organ systems develop at the same time, disruption of one system often occurs with disruption of others. Toward the end of the first trimester, it is possible to detect fetal heart tones by fetoscopy or ultrasonography.

Second Trimester. During the second trimester, from the end of the third month to the end of the sixth month, the height of the mother's uterus above the symphysis pubis is an indicator of fetal growth and approximate gestational age. Between 16 and 20 weeks, the mother begins to feel fetal movement. This feeling of life is referred to as **quickening**.

By the end of the sixth month, most of the fetal organ systems are complete and can function. The **fetus** is therefore considered viable, or capable of life outside the uterus, if given intensive environmental support. Fingers and toes are differentiated, rudimentary kidneys function, and the genitalia are defined. The fetus is covered with **vernix caseosa**, a cheeselike substance coating the skin. **Lanugo**, or fine hair, covers most of the body. These substances protect the thin, fragile skin and decrease in amount as the pregnancy nears its completion; thus, infants born before 38 weeks' gestation have more of these protective coverings than do full-term infants.

Third Trimester. During the last 3 months of gestation, the fetus grows to approximately 50 cm in length. Subcutaneous fat is stored, and weight increases to between 3.2 and 3.4 kg. The skin thickens, lanugo begins to disappear, and the fetal body becomes rounder and fuller.

A tremendous spurt in brain growth begins during this trimester and lasts well into the first few years of life. The central nervous system has established its total number of neurons and connections between neurons, and myelination of nerve fibres progresses at a rapid rate.

At the end of the third trimester, the normal fetus is physically able to make the transition from intrauterine to extrauterine life. The circulatory system, which bypasses the right side of the heart (which, in turn, supplies the lungs with oxygen), can change its circulation to include the lungs. The lungs are capable of maintaining the inflated state for gas exchange. The primitive temperature maintenance systems, reflexes, and sensory organs are ready for use.

Health Promotion

You can address many topics with a pregnant patient in order to protect her health and that of the fetus. Topics may vary, depending on the stage of pregnancy. Box 22-2 lists some of the many topics that you can address with pregnant women and their partners. You can make a significant difference in supporting the functions of young families. After an assessment of the couple's strengths and weaknesses, you can direct parents to available services to enhance their coping skills (Petch & Halford, 2008).

Transition from Intrauterine to Extrauterine Life

The transition from intrauterine to extrauterine life requires rapid changes in the newborn. You need to assess the newborn's ability to make these changes, and you should begin to plan before the birth for appropriate nursing interventions (Murray & McKinney, 2010). Circulatory, pulmonary, and

thermal changes all contribute to the infant's adaptation to neonatal life. Gestational age and development, exposure to depressant drugs before or during labour, and the newborn's own behavioural style also influence the adjustment to the external environment. Therefore, initial assessment encompasses a variety of physical and psychosocial elements. You can also provide early opportunities for the parents and infant to develop close emotional bonds.

Physical Changes

The most extreme physiological change occurs when the newborn leaves the in utero circulation and assumes independent respiratory functioning. Nursing care is directed at maintaining an open airway, stabilizing and maintaining body temperature, and protecting the newborn from infection. The most widely used assessment tool is the **Apgar score**, in which heart rate, respiratory effort, muscle tone, reflex irritability, and colour are rated in order to determine overall status. The Apgar assessment is generally conducted at 1 and 5 minutes after birth and may be repeated until the newborn's condition stabilizes. Table 22-1 outlines the scoring criteria of physiological functioning. A total score of 0 to 3 signifies severe distress, a score of 4 to 6 represents moderate difficulty, and a score of 7 to 10 indicates little difficulty in adjusting to extrauterine life. You can use the Apgar score to determine areas requiring further assessment and careful observation. In addition, you need to monitor and record the newborn's early elimination patterns (i.e., voiding and passage of meconium), as well as body temperature and other vital signs.

Psychosocial Changes

After conducting a physical evaluation and applying identification bracelets, promote the parents' and newborn's need for close physical contact. Early parent-child interaction encourages parent-child attachment or bonding. Physical factors (e.g., fatigue, hunger, and health) and emotional factors (e.g., needs for affection and for touch) are assessed.

Merely placing the family together does not promote closeness. The parents and newborn must be willing and able to respond to each other. Most healthy newborns are awake and alert for the first half-hour after birth. This is a good time for parent-child interaction to begin. Close body contact, often including skin-to-skin contact and breastfeeding, is a satisfying way for most families to start. If immediate contact is not possible, incorporate it into the care plan as early as possible, which may mean bringing the newborn to an ill parent or bringing the parents to an ill or premature child.

Bonding occurs when parents and newborn elicit reciprocal and complementary behaviour. Parental bonding behaviours include attentiveness and physical contact. Newborn bonding behaviour involves maintenance of physical contact with the parent. Preterm newborns, ill newborns, and ill mothers may have difficulty forming this bond if separation is prolonged; they need to be carefully assessed for any problems with attachment. The bonding process is further complicated if parents are unable to care for the infant. You should give the parents support throughout the early bonding process, particularly if the newborn or mother is ill or if the newborn is separated from the parents.

Health Risks

The removal of nasopharyngeal and oropharyngeal secretions with suction or a bulb syringe ensures airway patency.

* BOX 22-2 FOCUS ON PRIMARY HEALTH CARE

Health Promotion Topics for the Pregnant Patient

First Trimester Health Concerns

Nutrition

Mothers with good nutritional practices have fewer complications of pregnancy and childbirth and bear healthier babies than do mothers with poor nutritional intake (Murray & McKinney, 2010). Inadequate prenatal nutrition has been associated with lower birth weight (Oats & Abraham, 2010), and infants with low birth weight have an increased risk for learning disorders, temperament problems, neurological and motor impairment, and developmental delays. Folic acid (vitamin B₉) intake must be adequate before and during pregnancy; the recommended daily dose is 0.4 mg. Mothers should eat foods rich in folic acid, such as green leafy vegetables, liver, lentils, and asparagus. Folic acid intake is believed to be responsible for decreasing the incidence of neural tube defects (Health Canada, 2011). See Chapter 42 for a fuller description of the nutritional needs of the pregnant woman.

Teratogens

Agents capable of producing functional or structural damage to the developing fetus are called **teratogens**. You need to educate the mother about avoiding exposure to teratogenic agents. One such teratogen is the rubella virus, which can cause stillbirth or congenital anomalies, primarily when exposure occurs in the first trimester. Many drugs are teratogenic during the first trimester. You should assess the mother's past and current use of home remedies, medications (prescription and over-the-counter), and illegal drugs. The benefits of any drug needed to maintain the mother's health must be weighed against potential harm to the fetus.

Cigarette smoke and alcohol are also teratogens. Smoking during pregnancy has been shown to reduce birth weight and increase the incidence of premature birth, fetal death, and neonatal death (Murray & McKinney, 2010). It is also considered a risk factor for impaired growth and development among young children (Santrock, 2007). Alcohol consumed during pregnancy is known to cause fetal alcohol syndrome, fetal alcohol effects, and alcohol-related birth defects. Pregnant women must be educated about the risks of cigarette smoke and alcohol on the fetus.

Second Trimester Health Concerns

Preterm Labour

Preterm labour is labour that begins before the 37th week of pregnancy. With technological advances, it is possible for 500 g babies of

24 to 26 weeks' gestation to survive; however, the risk of morbidity and disability is significant. Causes of preterm labour are poorly understood and may be the result of maternal or fetal problems. Maternal risk factors include physiological stresses such as renal and cardiovascular disease, diabetes mellitus, and uterine and cervical abnormalities. Urinary tract infections greatly increase the risk of preterm labour. Because of dramatic changes occurring in the maternal renal system, it is possible for a mother to have an asymptomatic urinary tract infection. Voiding habits should be discussed with the mother during this time. Mothers living in poverty, smokers, and mothers receiving poor prenatal care are at higher risk for preterm labour (Kliegman et al., 2011). The presence of multiple fetuses and fetal infections are two of the potential fetal factors for preterm labour. Interventions to prevent preterm labour include medications, intravenous fluids, and bed rest.

Third Trimester Health Concerns

Choices of Birth Setting

In Canada, childbirth was gradually moved into hospital settings, starting in the early 1920s, and by 1950, approximately 76% of births occurred in hospitals (Mitchinson, 2002) because emergency backup was available in case of birth complications. Many hospitals have taken a family-centred approach to childbirth.

In some areas of the country, birthing centres are available for mothers who prefer a more homelike setting. Women delivering in this setting are required to attend childbirth classes, and the pregnancy must be considered low risk. Physicians and midwives with hospital privileges may attend births in these facilities. Mothers must understand that they may be transferred to a hospital if the conditions warrant.

A growing number of mothers choose to deliver at home when professional midwifery services are available. Control over the birth process and the desire for a more natural birth are common reasons why some mothers choose home births. Another reason is so that the entire family or other people close to the family can be part of the birth. You can support the mother by offering information and resources to help her choose the birth setting.

► TABLE 22-1 Apgar Scoring

Sign	Score 0	Score 1	Score 2
Heart rate	Absent	Slow, <100 bpm	>100 bpm
Respiratory effort	Absent	Irregular, slow, weak cry	Strong cry
Muscle tone	Limp	Some flexion of extremities	Strong flexion of extremities
Reflex irritability	No response	Grimace	Cry, sneeze
Colour	Blue, pale	Body pink, extremities blue	Completely pink

Adapted from Hockenberry, M. J., & Wilson, D. (2011). *Wong's nursing care of infants and children* (9th ed., p. 231). St Louis, MO: Mosby.

Newborns are susceptible to heat loss and cold stress (Kliegman et al., 2011). Because hypothermia increases oxygen needs, the newborn's body temperature must be stabilized and maintained. The newborn may be placed directly on the mother's abdomen and covered in warm blankets; dried and wrapped in warm blankets, with the head well covered; or

placed unclothed in an infant warmer with a temperature probe in place. For newborns unable to sustain adequate body temperature, isolettes and incubators, which supply radiant heat, are preferred.

Prevention of infection is a major concern in the care of the newborn, whose immune system is immature. Good

handwashing technique is the most important factor in protecting the newborn and yourself from infection. Once the blood and amniotic fluid have been removed from the infant's skin, you do not need to wear cover gowns while you provide care for the healthy newborn (Murray & McKinney, 2010). Other precautions include wearing gloves when touching mucous membranes or skin that is not intact (e.g., as a result of surgery or injury) and when drawing blood (e.g., heel stick).

The most commonly used prophylactic treatment against ophthalmic conjunctivitis is erythromycin (0.5%) because it prevents infections with *Neisseria gonorrhoeae* and other organisms, which can be transmitted during passage through an infected vaginal canal. This treatment should be applied during the newborn's initial assessment.

Vitamin K is administered in a single intramuscular injection shortly after birth. Vitamin K is important for the synthesis of prothrombin, necessary for clotting. Normally, the intestinal flora synthesizes vitamin K, and by about the third day, the infant should have enough intestinal flora to start to synthesize its vitamin K.

The stump of the moist umbilical cord is an excellent medium for bacterial growth. The cord should be cleansed with soap and water and dried at each diaper change. Until the stump dries and falls off, the diaper should be folded below the umbilicus to prevent accumulation of moisture.

Newborn

The neonatal period is the first month of life. During this stage, the newborn's physical functioning is mostly reflexive, and stabilization of the major organ systems is the body's primary task. Behaviour greatly influences interaction between the newborn and the environment and caregivers. For example, the average two-week-old newborn may smile and is able to regard the mother's face. The effect of these reflexive behaviours is generally a surge of feelings of love that prompt the mother to cuddle the baby.

You can apply your knowledge of this stage of growth and development to promote neonatal and parental health. If you understand, for example, that the newborn's cry is usually a response to an unmet need (such as hunger), you can assist parents in identifying ways to meet those needs, such as counselling the parents to feed their baby on demand rather than on a rigid schedule.

Physical Changes

A comprehensive nursing assessment is usually performed as soon as the newborn's physiological functioning is stable, generally within a few hours after birth. Measure the infant's height, weight, head circumference, temperature, pulse, and respirations, and observe general appearance, body functions, sensory capabilities, reflexes, and responsiveness.

The average newborn weighs 3400 g, is 50 cm in length, and has a head circumference of 35 cm. Up to 10% of birth weight is lost in the first few days after birth, primarily through fluid losses by respiration, urination, defecation, and low fluid intake. Birth weight is usually regained by the second week after birth, and a gradual pattern of increase in weight, height, and head circumference is evident. During the first month, weekly increases average 226 to 455 g in weight, 0.6 to 2.5 cm in length, and 2 cm in head circumference.

The newborn's heart rate ranges from 120 to 160 beats per minute. The average blood pressure is 85/54 mm Hg. The newborn's respiratory movements are primarily abdominal

and vary in rate and rhythm, with an average rate of 30 to 60 breaths per minute. The axillary temperature ranges from 36°C to 37.5°C and generally stabilizes within 24 hours after birth.

Normal physical characteristics include the continued presence of lanugo on the skin of the back; cyanosis of the hands and feet for the first 24 hours; and a soft, protuberant abdomen. Skin colour varies according to racial and genetic heritage and gradually changes during infancy. **Molding**, or overlapping of the soft skull bones, allows the fetal head to adjust to various diameters of the maternal pelvis and is a common occurrence with vaginal births. The bones readjust within a few days, producing a rounded appearance. The sutures and **fontanels** are usually palpable at birth. The diamond shape of the anterior fontanel and the triangular shape of the posterior fontanel between the unfused bones of the skull are shown in Figure 22-1.

To assess neurological function, observe the newborn's level of activity, alertness, irritability, responsiveness to stimuli, and reflexes. Normal reflexes include sucking, rooting, grasping, yawning, coughing, sneezing, hiccupping, blinking in response to bright lights, and startling (pulling arms and legs inward) in response to sudden, loud noises. An absence of any of these or other reflexes indicates **prematurity**, possible trauma, or central nervous system complications. Because the newborn depends largely on reflexes for survival and response to its environment, it is necessary to assess them. Figure 22-2 shows the tonic neck reflex: When newborns are lying supine, they reflexively turn the head to one side, extend the arm and leg on that side, and flex the opposite arm and leg.

Normal newborn behaviours include periods of sucking, crying, sleeping, and wakefulness. Movements are generally sporadic, but they are symmetrical and involve all four extremities. The relatively flexed fetal position of intrauterine life continues as the newborn attempts to maintain an enclosed, secure feeling. Newborns respond to sensory stimuli, particularly the primary caregiver's face, voice, and touch.

Except for the first hour after birth, when they are in a quietly alert state, newborns sleep almost continuously for the first 2 to 3 days to recover from the exhausting birth process. Thereafter, sleep periods vary from 20 minutes to 6 hours with little day-night differentiation.

Cognitive Changes

Early cognitive development begins with innate behaviour, reflexes, and sensory functions. Newborns initiate reflex activities and learn behaviours and desires. For example, newborns reflexively turn to the nipple (rooting) and learn that crying results in parents' response of feeding, diapering, and cuddling.

Sensory functions contribute to cognitive development in the newborn. At birth, children can fixate on moving objects about 20 to 25 cm from their faces (Hockenberry & Wilson, 2011). A preference for the human face is apparent. Auditory and vestibular (i.e., equilibrium) systems function from birth. These sensory capabilities allow newborns to elicit stimuli rather than simply receive them. Parents should be taught the importance of providing sensory stimulation, such as talking to their newborns and holding them to see their faces. This allows infants to seek or take in stimuli, thereby enhancing learning and promoting cognitive development.

Psychosocial Changes

During the first month of life, parents and newborns normally develop a strong bond that grows into a deep attachment.

A

B

Figure 22-1 Fontanels and suture lines. **Source:** Adapted from Hockenberry, M. J., & Wilson, D. (2011). *Wong's nursing care of infants and children* (9th ed., p. 245, Fig. 8-7). St Louis, MO: Mosby.

Interactions during routine care enhance or detract from the attachment process. The processes of feeding, changing, bathing, and comforting an infant promote interaction and provide a foundation for deep attachments. Early on, older siblings should have the opportunity to be involved with the

Figure 22-2 Tonic neck reflex. **Source:** Courtesy Paul Vincent Kuntz, Texas Children's Hospital.

Figure 22-3 Siblings should be encouraged to visit with the newborn as soon as possible. **Source:** Courtesy Elaine Polan, RNC, BSN, MS.

newborn. Family involvement helps support growth and development and promotes nurturing (Figure 22-3).

If parents or newborns experience health complications after birth, bonding may be compromised. Infants' behavioural cues may be weak or absent, and caregiving may be less mutually satisfying. Tired, ill parents have difficulty interpreting and responding to their infants' cues. Children who have congenital anomalies are often too weak to be responsive to parental cues and require special supportive nursing care. For example, infants born with heart defects may tire easily during feedings. They may rest frequently after several bursts of

sucking. They may awaken frequently, crying because they are hungry again. Mothers may think that they are inadequate as mothers or that the infants are being fussy. Both infants and mothers may feel frustrated. In this case, bonding is not enhanced and may even be reduced unless nursing intervention breaks the sequence of events.

For newborns, crying is a means of communication and provides cues to parents (Santrock, 2007). Although it can be a sign of distress, such as from pain, crying is an adaptive response to extrauterine life. Babies may cry because their diapers are wet, they are hungry, they want to be held, or they need a change in position or activity. Their crying may frustrate the parents if no cause is apparent. With help, parents can learn to recognize infants' cry patterns and take appropriate action when necessary (Herman & Le, 2007).

Health Risks

Hyperbilirubinemia is a condition in which an excessive amount of bilirubin accumulates in the blood, and it is characterized by a yellowish colouring of the skin, or jaundice. The accumulation occurs when the infant's immature liver is unable to balance the destruction of red blood cells with the use or excretion of by-products. The balance can be further upset by prematurity, inadequate intake during breastfeeding, excess production of bilirubin, certain disease states, or a disturbance in the liver. Bilirubin at high levels is highly toxic to neurons, and affected newborns are at risk for brain injury. Phototherapy is used to help break down the bilirubin for easier excretion. During phototherapy, the infant's eyes must be shielded because they can be damaged by the light. Because excretion of the extra bilirubin can cause watery stools, adequate fluid balance in the infant must be maintained.

Health Concerns

Screening. Coordinate screening tests and other laboratory tests as needed. Blood tests can determine **inborn errors of metabolism**. This term applies to genetic disorders caused by the absence or deficiency of a substance, usually an enzyme, essential to cellular metabolism that results in abnormal protein, carbohydrate, or fat metabolism. Although inborn errors of metabolism are rare, they account for a significant proportion of health problems in children. Neonatal screening can detect phenylketonuria (PKU), hypothyroidism, and galactosemia and thus allow appropriate treatment that can prevent permanent intellectual disability and other health problems. Routine screening of newborns for PKU is recommended (Kliegman et al., 2011). Other screening (e.g., for cystic fibrosis or hemophilia) may be necessary, depending on the family history.

Circumcision. Circumcision is controversial in this country and is not recommended as a routine procedure by the Canadian Paediatric Society (2011). The controversy surrounds the risks and benefits, especially with regard to pain control. Risks have been identified as hemorrhage, infection, adhesions, and meatal stenosis. Benefits include prevention of penile cancer, prevention of urinary tract infections, and preservation of male body image to be consistent with that of peers when circumcision is part of the culture (Hockenberry & Wilson, 2011). Parents must give informed consent before the procedure. Care of the circumcised site depends on the type of method used for the procedure. Circumcised newborns should be checked frequently for evidence of swelling, oozing, excessive bleeding, and the ability to void.

Infant

Infancy, the period from 1 month to 1 year of age, is characterized by dramatic physical growth and change. Psychosocial development advances, and interaction between infants and the environment, are greater and more meaningful. Infants who giggle and roll over in response to tickling are interacting more with their social environments than when they merely smile in response to a hug.

Physical Changes

Steady and proportional growth of the infant is more important than absolute growth values. The infant's growth can be compared with charts of normal age- and gender-related growth measurements. Using growth charts, you can also evaluate an infant's growth patterns by recording weight, length, and head circumference at selected intervals. Measurements recorded over time are the best way to monitor growth and identify problems. An infant with a growth problem may have measurements generally below the expected norms at all intervals or may experience an acute, brief interference with growth. An infant with a feeding problem or a genetic condition such as cystic fibrosis may have a weight below the expected norm.

Size increases rapidly during the first year; birth weight doubles in approximately 5 months and triples by 12 months. On average, weight gain is 680 g during the first 5 months and 340 g for months 7 to 12. Height increases an average of 2.5 cm during each of the first 6 months and 3.8 cm for the next 6 months. This 50% increase in birth height occurs primarily in the trunk, with the chest diameter approximating that of the head by the first birthday (Hockenberry & Wilson, 2011). The fontanels become smaller; the posterior fontanel closes at about 2 months.

Physiological functioning stabilizes, and by the end of the first year, the heart rate is 90 to 140 beats per minute, the blood pressure averages 95/65 mm Hg, and the respiratory rate is 30 to 35 breaths per minute. Patterns of body function also stabilize, as evidenced by predictable sleep, elimination, and feeding routines. Motor development proceeds steadily in a cephalocaudal direction (from the head toward the feet).

Cognitive Changes

The infant learns by experiencing and manipulating the environment. Developing motor skills and increasing mobility expand an infant's environment and, with developing visual and auditory skills, enhance cognitive development. For these reasons, Piaget (1952) named his first stage of cognitive development, which extends until around the third birthday, the **sensorimotor period** (see Chapter 21). Before the acquisition of language, the extraordinary development of the mind occurs through children's developing senses and motor abilities. Improved visual acuity and eye-hand coordination allow grasping and exploration of objects. In addition, rudimentary colour vision begins by 2 months and improves throughout the first year, making the environment more interesting to see and explore. Infants' hearing also improves, allowing localization and discrimination of sounds.

Infants need opportunities to develop and use their senses. Evaluate the appropriateness and adequacy of these opportunities. For example, ill or hospitalized infants may lack the energy to interact with their environments, and thus their cognitive development may be slowed. Infants need to be

stimulated according to their temperament, energy, and age. Use stimulation strategies that maximize development of infants while conserving their energy and orientation. An example of this approach is talking to an infant and encouraging him or her to suck on a pacifier while administering a tube feeding.

Language. Speech is an important aspect of cognition that develops during the first year. Infants proceed from crying, cooing, and laughing to imitating sounds, comprehending the meaning of simple commands, and repeating words with knowledge of their meaning. By age 1 year, children recognize their own names and have two- or three-word vocabularies, usually including “Da-Da,” “Ma-Ma,” and “no.” You can promote language development by encouraging mothers to name objects on which their infants’ attention is focused.

Psychosocial Changes

Separation. During their first year, infants begin to differentiate themselves from other people, understanding that they are separate beings capable of acting on their own. Initially, infants are unaware of the boundaries of self, but through repeated experiences with the environment, they learn where the self ends and the external world begins. As infants determine their physical boundaries, they begin to respond to others.

At 2 or 3 months of age, infants begin to smile responsively rather than reflexively. Similarly, they can recognize differences in people when their sensory and cognitive capabilities improve. By 8 months, most infants can differentiate a stranger from a familiar person and respond differently to the two. Close attachment to the primary caregivers, most often parents, is usually established by this age. Infants seek out these people for support and comfort during times of stress. The ability to distinguish self from others allows children to interact and socialize within their environments. By 9 months, for example, children play simple social games such as patty-cake and peek-a-boo. More complex interactive games such as hide-and-seek involving objects are possible by the age of 1 year. Erikson (1963) described the psychosocial developmental crisis for the infant as trust versus mistrust. If the infant’s physical and emotional needs are met, then the infant begins to develop a sense of security (see Chapter 21).

Assess the availability and appropriateness of experiences contributing to psychosocial development. Hospitalized infants may have difficulty establishing physical boundaries because of repeated bodily intrusions and painful sensations. Limiting these negative experiences and providing pleasurable sensations are interventions that support early psychosocial development. Extended separations from parents complicate the bonding process and increase the number of caregivers with whom the infant must interact. Ideally, the parents should provide the majority of care during hospitalization. When parents are not present, an attempt should be made to limit the number of caregivers who have contact with the infant and to follow the parents’ directions for care. These interventions will foster the infant’s continuing development of trust.

Play. Play is a meaningful set of activities through which individuals interact with their environment and relate to others. Play provides opportunities for the infant to develop many motor skills. Much of infant play is exploratory, inasmuch as infants use their senses to observe and examine their own bodies and objects of interest in their surroundings. For example, placing their toes in their mouths provides infants

with pleasure and information about their own body and helps form their early self-concept. Play becomes manipulative as children learn control of the hands. Adults can facilitate infant learning by planning activities that promote the development of milestones and by providing toys that are safe for infants to explore with the mouth and manipulate with the hands, such as rattles, blocks, stacking rings, and washable stuffed animals. Infants most frequently engage in solitary (one-sided) play but do enjoy watching others, particularly siblings. Infants need to be played with and stimulated through interactions with others.

Health Risks

Sudden Infant Death Syndrome. Sudden infant death syndrome (SIDS) is the sudden and unexpected death of an apparently healthy infant. SIDS is rare before 1 month of age, but its incidence peaks among infants between 2 and 4 months of age, and it can occur in infants up to a year old. Three babies die of SIDS every week in Canada (Canadian Foundation for the Study of Infant Deaths, 2010). The cause of SIDS is not understood, but the Public Health Agency of Canada (2011a) recommends the following precautions:

- Infants should sleep on their backs on a firm, flat surface alone (i.e., sharing any sleeping surface with another person is hazardous to the infant).
- A smoke-free environment should be provided before and after birth.
- A baby’s crib must be free of such clutter as toys, bumper pads, pillows, blankets, and other loose bedding.
- The crib should be placed next to the adult’s bed for the first six months.
- The infant should be dressed lightly to avoid overheating.
- Mothers should breastfeed if possible.

Accidental Injury. Injury is a major cause of death in children 6 to 12 months old. An understanding of the major developmental accomplishments during this period helps you plan for injury prevention. Box 22-3 lists the main types of injuries occurring in this age group and possible prevention strategies.

Child Maltreatment. You need to be aware that child maltreatment can occur during any stage of a child’s life, beginning in infancy. *Child maltreatment* refers to violence, emotional or sexual mistreatment, or neglect of a child or adolescent. More children suffer from neglect than from any other type of maltreatment. Many suffer from more than one type of child maltreatment. Approximate numbers of reported cases of child maltreatment of children in Canada, not including Quebec, show that for every 1000 children there were six cases of neglect, five cases of physical maltreatment, three cases of emotional maltreatment, and one case of sexual maltreatment (Trocmé et al., 2005). Protection of children from maltreatment comes under the jurisdiction of a province or territory. If you suspect any type of maltreatment of children, you are legally required to report it. Box 22-4 includes possible signs and symptoms of child maltreatment. These indications apply to children from infancy through adolescence.

A combination of signs and symptoms or a pattern of injury should arouse suspicion. It is important for you to be aware of certain birthmarks (e.g., Mongolian spots, which are flat, dark birthmarks that may look like bruises) and cultural practices (e.g., coining, in which the skin is rubbed or scratched with a coin to improve circulation or restore balance) that may mimic signs of maltreatment.

► BOX 22-3 Injury Prevention During Infancy

Age: Birth to 4 Months

Major Developmental Accomplishments

Involuntary reflexes, such as the crawling reflex, may propel infant forward or backward, and the startle reflex may cause the body to jerk.

The infant may roll over.

Eye-hand coordination improves, and the voluntary grasp reflex increases.

Injury Prevention

Aspiration

Aspiration is not as great a danger in this age group as in others, but you should begin to practise safeguarding early (see "Age: 5 to 7 Months" section).

Never shake baby powder directly on the infant; place powder in your hand and then on infant's skin. Store container closed and out of the infant's reach.

Hold the infant for bottle feeding; do not prop the bottle.

Know emergency procedures for choking.

Use pacifiers with one-piece construction and loop handle.

Suffocation and Drowning

Keep all plastic bags stored out of the infant's reach; discard large plastic garment bags after tying them in a knot.

Do not cover the infant's mattress with plastic.

Use a firm mattress; use no pillows or loose bedding.

Make sure crib design follows federal regulations and mattress fits snugly; crib slats should be no farther than 6 cm apart.

Position the crib away from other furniture and away from radiators.

Do not tie a pacifier on a string around the infant's neck.

Remove bibs at bedtime.

Never leave the infant alone in a bath.

If the infant is younger than 12 months, do not leave him or her alone on an adult- or youth-sized mattress or on "beanbag"-type pillows.

Falls

Always raise crib rails.

Never leave the infant on a raised, unguarded surface.

When in doubt as to where to place the child, use the floor.

Restrain the child in an infant seat, and never leave him or her unattended while the seat is resting on a raised surface.

Avoid using a high chair until the child can sit well with support.

Poisoning

Poisoning is not as great a danger in this age group as in others, but you should begin to practise safeguards early (see "Age: 5 to 7 Months" section).

Burns

Install smoke detectors in the home.

Use caution when warming formula in a microwave oven; always shake the bottle and check temperature of liquid before feeding.

Check bath water temperature.

Do not pour hot liquids when the infant is close by (e.g., sitting on your lap).

Do not smoke cigarettes around the child.

Do not leave infant in the sun for more than a few minutes; keep exposed areas covered.

Wash flame-retardant clothes according to label directions.

Use cool-mist (rather than hot-mist) vaporizers.

Do not leave the child in a parked car.

Check the surface heat of the car restraint before placing the child in it.

Motor Vehicles

Transport the infant in a federally approved, rear-facing infant seat, in the back seat* (Figure 22-4).

Never place an infant seat in the front passenger seat with an air bag.*

Do not place the child in a carriage or stroller behind a parked car.

Do not leave infant in a vehicle on a warm day.

Bodily Damage

Avoid sharp, jagged objects.

Keep diaper pins closed and away from the infant.

Never shake a baby (which can cause shaken baby syndrome); advise caregivers to seek help if they feel irritated or overwhelmed by a baby's crying.

Age: 5 to 7 Months

Major Developmental Accomplishments

The infant rolls over.

The infant sits momentarily.

The infant grasps and manipulates small objects.

The infant picks up a dropped object.

The infant has well-developed eye-hand coordination.

The infant can focus on and locate very small objects.

The infant's tendency to put objects in his or her mouth is very prominent.

The infant can push up on hands and knees.

The infant crawls backward.

Injury Prevention

Aspiration

Keep buttons, beads, syringe caps, and other small objects out of the infant's reach.

Keep the floor free of any small objects.

Do not feed the infant hard candy, nuts, food with pits or seeds, or whole or circular pieces of hot dog.

Exercise caution when giving the infant teething biscuits, because large chunks may be broken off and aspirated.

Do not feed the infant while he or she is lying down.

Inspect toys for removable parts.

Suffocation

Keep all latex balloons out of the child's reach.

Remove all crib toys that are strung across the crib or playpen when the child begins to push up on hands or knees or is five months old.

Keep baby powder and baby oil, if used, out of the child's reach.

Falls

Restrain the child in a high chair.

Keep crib rails raised to their full height.

Do not use baby walkers (baby walkers are no longer sold in or imported to Canada because of the high rate of injuries that they cause).

Poisoning

Make sure that paint for furniture or toys does not contain lead.

Hang plants, or place them on high surfaces rather than on the floor.

Store coinlike batteries and any toxic substances, such as cleaning fluid, paints, and pesticides, out of the reach of babies on a high shelf or in a locked cabinet.

Discard used containers of poisonous substances.

Do not store toxic substances in food containers.

*Further information available from Transport Canada (2011) and Health Canada (2010b).

► BOX 22-3 Injury Prevention During Infancy—cont'd

Store medication in a locked cabinet and keep cosmetic and personal products out of the child's reach.

Know the telephone number of the local poison control centre (usually listed in the beginning of telephone directories).

Burns

Keep faucets out of reach.

Place hot objects (candles, incense) on high surfaces.

Limit the child's exposure to sun; apply sunscreen.

Motor Vehicles

See "Age: Birth to 4 Months" section.

Bodily Damage

Give the child toys that are smooth and rounded, preferably made of natural wood or plastic.

Avoid long, pointed objects as toys.

Avoid toys that are excessively loud.

Keep sharp objects out of the infant's reach.

See also the "Age: Birth to 4 Months" section.

Age: 8 to 12 Months

Major Developmental Accomplishments

The child crawls and creeps.

The child stands, holding on to furniture.

The child stands alone.

The child cruises around furniture.

The child walks.

The child climbs.

The child pulls on objects.

The child throws objects.

The child is able to pick up small objects and has pincer grasp.

The child explores objects by putting them in his or her mouth.

The child dislikes being restrained.

The child explores away from parents.

The child's understanding of simple commands and phrases increases.

Injury Prevention

Aspiration

Keep small objects out of the reach of children.

Feed very small pieces of solid table food.

Do not use beanbag toys or allow the child to play with dried beans.

See also the "Age: 5 to 7 Months" section.

Suffocation and Drowning

Keep doors of appliances (ovens, dishwashers, refrigerators, coolers, and front-loading clothes washers and dryers) closed at all times.

If you are storing an unused appliance, such as a refrigerator, remove the door.

Supervise contact with inflated balloons; immediately discard popped balloons, and keep uninflated balloons out of children's reach.

Fence in swimming pools.

Always supervise the child when near any source of water, such as baths, cleaning buckets, drainage areas, and toilets.

Keep bathroom doors closed.

Eliminate unnecessary pools of water.

Keep one hand on the child at all times when he or she is in the tub.

Falls

Fence stairways at the top and bottom if the child has access to either end.

Dress the child in safe shoes (soles that do not "catch" on the floor, tied shoelaces) and clothing (pant legs that do not touch the floor).

Ensure that furniture is sturdy enough for the child to hold while pulling himself or herself to a standing position and cruising.

Poisoning

Never call medications "candy."

Do not administer medications unless they are prescribed by a practitioner.

Put away medications and poisons immediately after use; put child-protector caps on properly.

Keep phone number for poison control centre readily available.

Burns

Place guards in front of or around any heating appliance, fireplace, or furnace.

Keep electrical wires hidden or out of the child's reach.

Place plastic guards over electrical outlets; place furniture in front of outlets.

Keep hanging tablecloths out of reach (the child may pull down hot liquids or heavy or sharp objects).

Adapted from Hockenberry, M. J., & Wilson, D. (2011). *Wong's nursing care of infants and children* (9th ed., pp. 510–511). St Louis, MO: Mosby.

Health Concerns

Nutrition. The quality and quantity of nutrition influence the infant's growth and development. Help parents select a nutritionally adequate diet for their infant. Nutrition is affected by many variables (e.g., culture, food preferences, slow eating, or food allergies), and no diet is effective for all children or for one age group.

Feeding Alternatives. Supplying essential nutrients to the infant is an important goal. Support the parents' choice of feeding methods and facilitate a successful feeding process (Box 22-5). Breastfeeding is considered the most complete nutritional source until the infant is about six months of age. Breast milk contains protein, fats, and carbohydrates, as well as immunoglobulins that bolster the infant's ability to resist infection. Breastfeeding has been associated with enhanced cognitive development and a decreased frequency of respiratory tract illnesses, type 2 diabetes, gastroenteritis, otitis media, and food allergies (Health Canada, 2007a; Hockenberry & Wilson, 2011).

Figure 22-4 Federally approved infant car restraint. Note that the seat is rear facing in the back seat. **Source:** Courtesy Elaine Polan, RNC, BSN, MS.

► BOX 22-4 Clinical Manifestations of Potential Child Maltreatment**Physical Neglect****Suggestive Physical Findings**

Failure to thrive (infants), signs of malnutrition (e.g., unhealthy looking skin and hair, sunken eyes or cheeks), evidence of poor health care

Poor personal hygiene, especially of teeth; unclean or inappropriate dress

Frequent injuries resulting from lack of supervision

Suggestive Behaviours

Dull and inactive (infants)

Self-stimulatory behaviours, such as finger sucking or rocking

Begging or stealing food, vandalism, or shoplifting

Absenteeism from school

Drug or alcohol addiction

Emotional Maltreatment and Neglect**Suggestive Physical Findings**

Failure to thrive

Feeding disorders, such as rumination

Enuresis (bed wetting after toilet training has been established)

Sleep disorders

Suggestive Behaviours

Self-stimulatory behaviours such as biting, rocking, sucking

Stranger anxiety and lack of social smile (infants)

Withdrawal and unusual fearfulness

Antisocial behaviour, such as destructiveness, stealing, cruelty

Extremes of behaviour, such as overcompliance, passivity, aggressiveness, or being demanding

Lags in emotional and intellectual development, especially language

Suicide attempts

Physical Maltreatment**Suggestive Physical Findings**

Bruises and welts on face, lips, mouth, back, buttocks, thighs, or areas of torso

Regular patterns on skin that are descriptive of certain objects, such as belt buckle; hand; wire hanger; chain; wooden spoon; squeeze or pinch marks; round cigar or cigarette burns; burns in the shape of an iron, radiator, or electric stove burner

Burns, injuries, fractures, lacerations, or bruises in various stages of healing on soles of feet, palms of hands, back, or buttocks

Presence of symmetrical burns in the absence of "splash" marks

Unusual symptoms, such as abdominal swelling, pain, and vomiting from punching

Marks such as those resembling human bites, or pulling out of hair

Unexplained repeated poisoning or unexplained sudden illness

Suggestive Behaviours

Wariness of physical contact with adults

Apparent fear of parents or of going home

Lying very still while surveying environment, lack of reaction to frightening events

Inappropriate reaction to injury, such as failure to cry from pain

Apprehensiveness when hearing other children cry

Indiscriminate friendliness and displays of affection, superficial relationships

Acting-out behaviour, attention-seeking behaviours

Withdrawn behaviour

Sexual Maltreatment**Suggestive Physical Findings**

Bruises, bleeding, lacerations, or irritation of external genitalia, anus, mouth, or throat

Torn, stained, or bloody underclothing

Pain on urination or pain, swelling, and itching of genital area; penile discharge; unusual odour in the genital area

Sexually transmitted infection, nonspecific vaginitis, venereal warts, or presence of sperm

Difficulty in walking or sitting

Recurrent urinary tract infections

Pregnancy in a young adolescent

Suggestive Behaviours

Sudden emergence of sexually related problems, including excessive or public masturbation, age-inappropriate sexual play, promiscuity, or overtly seductive behaviour

Withdrawn behaviour, excessive daydreaming, preoccupation with fantasies, especially in play

Poor relationships with peers

Sudden changes, such as anxiety, loss or gain of weight, clinging behaviour

In incestuous relationships, a child's excessive anger at one parent for not protecting the child from the other parent

Regressive behaviour, such as bed-wetting or thumb-sucking

Sudden onset of phobias or fears, particularly fears of the dark, men, strangers, or particular settings or situations (e.g., undue fear of leaving the house, of staying at the day care centre, or of staying at the babysitter's house)

Running away from home

Substance abuse, particularly of alcohol or mood-elevating drugs

Profound and rapid personality changes, especially extreme depression, hostility, and aggression (often accompanied by social withdrawal)

Rapidly declining school performance

Suicidal attempts or ideation about suicide

Adapted from Hockenberry, M. J., & Wilson, D. (2011). *Wong's nursing care of infants and children* (9th ed., p. 636). St Louis, MO: Mosby.

If breastfeeding is not possible or not desired by the parent, an acceptable alternative is commercially prepared formula that is fortified with iron. Formulas are convenient, contain standard ingredients, and are also fortified with vitamins and minerals. Cow's milk and imitation milks are not recommended in the first year, because infants are not able to properly digest the contained fat. Cow's milk also contains more sodium and protein and less iron and essential nutrients than does formula (Hockenberry & Wilson, 2011). Because cow's milk has low levels of iron and high levels of calcium and

phosphorus, absorption of iron may be decreased, causing anemia.

The average 1-month-old infant takes approximately 540 to 630 mL of breast milk or formula per day. This amount increases slightly during the first 6 months and decreases when solid foods are introduced. The amount of formula per feeding and the number of feedings vary among infants.

Developmentally, infants are not ready for solid food until 6 months of age. Before 6 months, the infant's gastrointestinal tract cannot handle the complex nutrients in solid food, and

* BOX 22-5 RESEARCH HIGHLIGHT

Breastfeeding

Research Focus

Fathers are a key source of breastfeeding support. You can play an important role in promoting breastfeeding by including fathers in breastfeeding education and interventions.

Research Abstract

Rempel and Rempel (2010) explored the role of involved fathers in breastfeeding families. The qualitative study was performed with a small sample of fathers ($n=21$) in two regions of Ontario. The researchers found that the fathers viewed breastfeeding as a team endeavour. The fathering role consisted of supporting breastfeeding by becoming breastfeeding savvy, using their knowledge of breastfeeding to encourage and assist mothers in breastfeeding, valuing the breastfeeding mothers, and sharing housework and child care. The researchers concluded that nurses and other health care providers need to assist fathers in recognizing their unique contributions to the breastfeeding team.

Evidence-Informed Practice

- Assess the breastfeeding support of new mothers.
- Include the mother's partner in supporting and offering praise to the breastfeeding mother.
- Include fathers in breastfeeding education and interventions.
- Promote the unique role of the father on the breastfeeding team.

Reference: Rempel, L. A., & Rempel, J. K. (2010). The breastfeeding team: The role of involved fathers in the breastfeeding family. *Journal of Human Lactation*. Advance online publication. doi:10.1177/0890334410390045.

the extrusion reflex causes food to be pushed out of the mouth. Also, early introduction to solid foods may cause food allergies.

Cereals and well-cooked and puréed fruits, vegetables, and meats eaten during the second 6 months of life provide iron and additional sources of vitamins. These nutrients become especially important when infants stop consuming breast milk or formula and begin drinking whole cow's milk after the first birthday. Because the amount and frequency of feedings vary among infants, discuss differing feeding patterns with parents.

Honey has been used to sweeten water and coat pacifiers. However, honey should not be given to infants younger than one year because of the potential for infant botulism poisoning (Kliegman et al., 2011).

Supplementation. The need for dietary vitamin and mineral supplements depends on the infant's diet. Full-term infants are born with some iron stores. The breastfed infant absorbs adequate iron from breast milk during the first 4 to 6 months of life. After age 6 months, iron-fortified cereal is generally considered an adequate supplemental source. Because iron in formula is less readily absorbed than that in breast milk, formula-fed infants should receive iron-fortified formula throughout the first year. All Canadian infants who are breastfed need to receive a daily 400 IU vitamin D supplement to prevent rickets (Health Canada, 2007a).

Adequate concentrations of fluoride to protect against dental caries are not available in human milk, so fluoridated water or supplemental fluoride is generally recommended. The presence of fluoride in formula depends on the type of

formula and the source of water used in preparing the concentrated forms. Fluoride supplementation may be necessary.

Overfeeding and Infant Obesity. The association between overfeeding, infant obesity, and later adult obesity is controversial. However, early feeding experiences can influence later eating habits. You should therefore emphasize balanced nutrition and good dietary habits through feeding experiences mutually satisfying for parents and infant. Eating habits are frequently affected by the family's sociocultural background. Because some cultures consider a fat baby to be a sign of good mothering, any suggestion to limit intake or slow weight gain may be seen as a threat. It is important for you to develop an understanding of cultural influences to develop effective nursing interventions. For example, breastfeeding is associated with a reduced risk of childhood obesity, but some cultural beliefs may promote formula feeding. A traditional belief in the Somali culture is that breast milk spoils in the breast after several hours (Steinman et al., 2009). Nurses working with pregnant or new mothers with a Somali cultural background need to educate these women and the Somali community about breastfeeding to counteract the cultural myth.

Dentition. The average age at which the first tooth erupts is 7 months, but considerable variation exists among infants because of their genetic endowment. Occasionally, an infant is born with a tooth, whereas others remain toothless at 1 year. The order of tooth eruption is fairly predictable: the lower central incisors are first to appear, closely followed by the upper central incisors. Most 1-year-olds have six teeth.

Teething may result in considerable discomfort for some infants and little or none for others. The inflammation of the gums before the tooth emerges may result in a low-grade fever and irritability. Some infants exhibit increased drooling, biting, or finger sucking. Biting on a frozen teething ring or ice cube wrapped in a washcloth may be soothing. Over-the-counter teething medications to rub on the inflamed gums and appropriate doses of acetaminophen are helpful when the infant is irritable and has difficulty eating or sleeping.

Most dentists recommend that parents cleanse their infant's teeth after each feeding. The parent can place a clean, wet washcloth or piece of gauze over a finger and use it to wipe the infant's teeth. Because of the risk of developing dental caries, discourage prolonged breast- or bottle-feeding, especially just before the infant goes to sleep because the infant is likely to leave milk in the mouth and around the teeth. The infant should never go to bed with a bottle of juice or milk (Kliegman et al., 2011).

Immunizations. The widespread use of immunizations has resulted in the dramatic decline of infectious diseases since the 1950s and is therefore a most important factor in health promotion during childhood. Although most immunizations can be given to people of any age, the Public Health Agency of Canada (2006) recommended that the administration of the primary series begin soon after birth and be completed during early childhood. The Canadian national immunization guidelines for infants and children, which are currently under review, are presented in Table 22-2. However, publicly funded immunization schedules vary from province to province or territory. Therefore, you must know the specific immunization schedule for your jurisdiction. The Public Health Agency of Canada (2011b) maintains an online tool where parents can create a personal immunization schedule for their child based on age and provincial or territorial residence. Parents must receive instructions regarding the potential side effects of

► TABLE 22-2 Canadian Routine Immunization Schedule for Infants and Children

Age at Vaccination	DTaP-IPV	Hib	MMR	Var	HB	Pneu-C-7	Men-C	Tdap	Inf
Birth					Infancy: 3 doses				
2 months	⊛	+			★	◆	⊙		
4 months	⊛	+				◆	(⊙)		
6 months	⊛	+				◆	⊙ or		6–23 months
12 months			■	●	or	◆ 12–15 months	⊙ if not yet given		●
18 months	⊛	+	■ or						1–2 doses
4–6 years	⊛		■						
14–16 years					Preteen/teen: 2–3 doses		⊙ if not yet given	▲	

Legend

() Symbols with brackets around them imply that these doses may not be required, depending upon the age of the child or adult. Refer to the relevant chapter (in Public Health Agency of Canada, 2006) for that vaccine for further details.

⊛ Diphtheria, tetanus, a cellular pertussis, and inactivated polio virus vaccine (DTaP-IPV): DTaP-IPV(± Hib) vaccine is the preferred vaccine for all doses in the vaccination series, including completion of the series in children who have received one or more doses of DPT (whole cell) vaccine (e.g., recent immigrants). Year dose can be omitted if the fourth dose was given after the fourth birthday.

★ Haemophilus influenzae type b conjugate vaccine (Hib): The Hib schedule shown is for the Haemophilus b capsular polysaccharide-polyribosylribitol phosphate (PRP) conjugated to tetanus toxoid (PRP-T). For catching up, the number of doses depends on the age at which the schedule is begun (see Public Health Agency of Canada, 2006, "Haemophilus Vaccine" chapter). Not usually required past age 5 years.

■ Measles, mumps, and rubella (MMR) vaccine: A second dose of MMR vaccine is recommended for children at least 1 month after the first dose for the purpose of better measles protection. For convenience, options include giving it with the next scheduled vaccination at 18 months of age or at school entry (4–6 years) (depending on the provincial or territorial policy) or at any intervening age that is practical.

• Varicella vaccine (Var): children aged 12 months to 12 years should receive one dose of varicella vaccine. Susceptible individuals ≥13 years of age should receive two doses at least 28 days apart.

★ Hepatitis B vaccine (HB): hepatitis B vaccine can be routinely given to infants or preadolescents, depending on the provincial or territorial policy. For infants born to chronic carrier mothers, the first dose should be given at birth (with hepatitis B immunoglobulin); otherwise, the first dose can be given at 2 months of age to fit more conveniently with other routine infant immunization visits. The second dose should be administered at least 1 month after the first dose, and the third at least 2 months after the second dose, but these may fit more conveniently into the 4- and 60-month immunization visits. A two-dose schedule for adolescents is an option (see Public Health Agency of Canada, 2006, "Hepatitis B Vaccine" chapter).

◆ Pneumococcal conjugate vaccine-7-valent (Pneu-C-7): Recommended for all children under 2 years of age. The recommended schedule depends on the age of the child when vaccination is begun (see Public Health Agency of Canada, 2006, "Pneumococcal Vaccine" chapter).

□ Pneumococcal polysaccharide-23-valent (Pneu-P-23): Recommended for all adults ≥65 years of age (see Public Health Agency of Canada, 2006, "Pneumococcal Vaccine" chapter).

⊙ Meningococcal C conjugate vaccine (Men-C): Recommended for children under 5 years of age, adolescents, and young adults. The recommended schedule depends on the age of the individual (see Public Health Agency of Canada, 2006, "Meningococcal Vaccine" chapter) and the conjugate vaccine used. At least one dose in the primary infant series should be given after 5 months of age. If the provincial or territorial policy is to give Men-C to persons ≥12 months of age, one dose is sufficient.

▲ Diphtheria, tetanus, acellular pertussis vaccine—adult or adolescent formulation (Tdap): A combined adsorbed "adult type" preparation for use in people ≥7 years of age; contains less diphtheria toxoid and pertussis antigens than preparations given to younger children and is less likely to cause reactions in older people.

❖ Diphtheria, tetanus vaccine (Td): A combined adsorbed "adult type" preparation for use in people ≥7 years of age; contains less diphtheria toxoid antigen than preparations given to younger children and is less likely to cause reactions in older people. It is given to adults not immunized in childhood as the second and third doses of their primary series and subsequent booster doses; Tdap is given only once under these circumstances, as it is assumed that previously unimmunized adults will have encountered *Bordetella pertussis* and have some preexisting immunity.

● Influenza vaccine (Inf): Recommended for all children 6–23 months of age and all persons ≥65 years of age. Previously unvaccinated children <9 years of age require two doses of the current season's vaccine with an interval of at least 4 weeks. The second dose within the same season is not required if the child received one or more doses of Influenza vaccine during the previous Influenza season (see Public Health Agency of Canada, 2006, "Influenza Vaccine" chapter).

✦ Inactivated polio virus (IPV).

From Public Health Agency of Canada. (2006). *Canadian immunization guide: Seventh edition—2006*. Retrieved from <http://www.phac-aspc.gc.ca/publicat/cig-gci/index-eng.php>. Reproduced with permission of the Minister of Public Works and Government Services Canada, 2008.

immunizations. Minor side effects may occur, but serious reactions are rare. High fever and extreme irritability should be reported to the health care provider.

As a result of complacency and fear regarding the side effects of certain vaccines, especially diphtheria and tetanus toxoids and pertussis vaccine (DTP), not all children receive appropriate immunizations (Leitch, 2007). An important role for you is to discuss the importance of vaccination for infants

and children, provide up-to-date information to parents, and encourage them to make an informed decision for their children. General contraindications to vaccination include moderate illness, allergic response to a previous dose of a particular vaccine, and with live vaccines only, pregnancy, immunosuppression, and taking high doses of corticosteroids.

Sleep. Sleep patterns vary among infants, many having their days and nights "mixed up" until 3 to 4 months of age.

► **TABLE 22-3** Selected Sleep Disturbances During Infancy and Early Childhood

Disorder and Description	Management
Nighttime Feeding Colic, irritability Prolonged need for bottle or breastfeeding at night Going to sleep at the breast or with a bottle Irregular sleep patterns Returning to sleep after feeding; other comfort measures (e.g., rocking or holding) are usually ineffective	Soothe, rock for brief periods, offer pacifier. Gradually increase daytime feeding intervals to 4 hours or more. Offer last feeding as late as possible at night. Gradually increase amount of fluid during day. Offer no bottles in bed. Put child to bed when awake. When child is crying, check at progressively longer intervals each night; reassure child but do not hold, rock, take to parent's bed, or give bottle or pacifier.
Developmental Night Crying Child aged 6–12 months with undisturbed nighttime sleep now awakes abruptly; awakening may be accompanied by nightmares	Be assured that this phase is temporary. Enter room immediately to check on child, but keep reassurances brief. Avoid feeding, rocking, taking to parent's bed, or any other routine that may initiate trained nighttime crying.
Trained Night Crying (Inappropriate Sleep Associations) Child typically falls asleep in a place other than own bed (e.g., rocking chair or parent's bed) and is brought to own bed while asleep; on awakening, cries until usual routine is instituted (e.g., rocking)	Put child in own bed when child is awake. If possible, arrange sleeping area separate from other family members. Check crying child at progressively longer intervals each night; reassure child but do not resume usual routine.
Refusal to Go to Sleep Child resists bedtime and comes out of room repeatedly Nighttime sleep may be continuous, but frequent awakenings and refusal to return to sleep may occur and become a problem if parent allows child to deviate from usual sleep pattern	Evaluate whether bedtime is too early (child may resist sleep if not tired). Adapt consistent bedtime routine. If child persists in leaving bedroom, close door for progressively longer periods. Reinforce positive behaviour.
Nighttime Fears Child resists going to bed or wakes during the night because of fears Child seeks parent's physical presence and falls asleep easily with parent nearby Overwhelming fears	Evaluate whether bedtime is too early (child may fantasize when he or she has nothing to do but think in a dark room). Calmly reassure the frightened child; keeping a night light on may be helpful. Use reward system with child to provide motivation to deal with fears. Avoid patterns that can lead to additional problems (e.g., sleeping with child or taking child to parent's room). If child's fear is overwhelming, consider desensitization (e.g., progressively spending longer periods of time alone); obtain professional help for protracted fears. Distinguish between nightmares and sleep terrors (confused partial arousals).

By that age, most infants sleep between 9 and 11 hours a night. Total daily sleep averages 15 hours. Most infants take one or two naps a day by the end of the first year. Sleep disturbances with a physiological basis are rare, with the possible exception of colic. Common sleep disturbances are described in Table 22-3.

Toddler

Toddlerhood ranges from 12 to 36 months. Toddlers have increasing independence, physical mobility, and cognitive abilities. Toddlers become aware of their abilities to control their environments and are pleased with successful efforts. This success leads them to continue attempting to control their environments. Unsuccessful attempts at control may result in the toddler refusing to do something, saying no frequently, or engaging in temper tantrums.

Physical Changes

The rapid development of motor skills allows toddlers to participate in self-care activities such as feeding, dressing, and toileting. Initially, toddlers walk with a broad stance and gait,

protuberant abdomen, and arms out to the sides for balance. Soon they begin to navigate stairs, using a rail or the wall to maintain balance. Locomotion skills eventually include running, jumping, standing on one foot for several seconds, and kicking a ball. Most toddlers can ride tricycles, climb ladders, and run well by their third birthday.

Fine motor capabilities move from scribbling spontaneously to drawing circles and crosses accurately. By age three years, children draw simple stick people and can usually stack a tower of small blocks. Increased locomotion skills, the ability to undress, and development of sphincter control allow toilet training if a toddler has developed the necessary language and cognitive abilities. Parents often consult nurses for an assessment of readiness for toilet training. A child's recognition of the urge to urinate and defecate is a crucial component in the child's mental readiness. At this stage, children usually show a willingness to please parents and take pride in their accomplishments (Santrock, 2007). You must remind parents that patience, consistency, and a nonjudgemental attitude, in addition to child readiness, are essential for successful toilet training.

The cardiopulmonary system becomes stable in the toddler years. The heart and respiratory rates slow to an average of 110 beats and 25 breaths per minute, respectively, and the blood pressure varies slightly from infancy. The average blood pressure in toddlers is 90/50 mm Hg.

The anterior fontanel closes between 12 and 18 months of age, ending the period of the most rapid growth of the skull and brain. However, head circumference should be measured routinely until a toddler is 3 years of age.

The rate of increase in a toddler's weight and length slows. By age 2.5 years, children's weights are four times the birth weight. Height during the toddler years increases by approximately 7.5 cm a year, mainly as a result of increases in leg length. The average height of 2-year-olds is 85 cm. Slowed growth rates are accompanied by decreased caloric need, and smaller food intake leads some parents to worry about the adequacy of dietary intake. Parents need encouragement to offer appropriate servings of food from *Eating Well With Canada's Food Guide* (Health Canada, 2007b) and to avoid force-feeding or allowing children to fill up on foods that have high levels of fat and sugar. You can reassure parents that a child's nutrition is adequate by demonstrating the child's satisfactory status on a growth chart.

Cognitive Changes

Toddlers' completion of the development of **object permanence**, their ability to remember events, and their beginning ability to put thoughts into words at about 2 years of age signal their transition to Piaget's (1952) **preoperational thought** stage of cognitive development (see Chapter 21). Toddlers recognize that they are separate beings from their mothers, but they are unable to assume another person's point of view. They use symbols to represent objects, places, and people. This function is demonstrated when children imitate the behaviour of another person that they viewed earlier (e.g., pretend to shave like daddy), pretend one object is another (e.g., pretend that a doll is a baby), and use language to stand for absent objects (e.g., request a bottle).

Language. An 18-month-old child uses approximately 50 words (Santrock, 2007). A 24-month-old child has a vocabulary of up to 200 words and is generally able to speak in two-word sentences. "Who's that?" and "What's that?" typify questions asked during this period. First-person expressions such as "Me do it" and "That's mine" demonstrate 2-year-old children's use of pronouns and desire for independence and control. Despite the expanded vocabulary of older toddlers, the word they use most often is no until well into the third year. Offering choices to toddlers helps reduce their sense of frustration and builds their sense of independence (Santrock, 2007).

Because children's moral development is closely associated with their cognitive abilities, the moral development of toddlers is only beginning and is also egocentric. Toddlers do not understand concepts of right and wrong. However, they understand that some behaviours bring pleasant results and others elicit unpleasant results. Therefore, until toddlers achieve a higher level of cognitive function, they behave simply to avoid the unpleasant and seek out the pleasant (Hockenberry & Wilson, 2011).

Psychosocial Changes

According to Erikson (1963), a sense of autonomy emerges during the toddler years (see Chapter 21). Children strive for independence by using their developing muscles to do

everything for themselves and control their bodily functions. Their strong wills are frequently exhibited in negative behaviour when caregivers attempt to direct their actions; for example, temper tantrums may result when toddlers are frustrated by parental restrictions. Parents need to provide toddlers with graded independence, allowing them to do things that do not result in harm to themselves or others. This strategy prevents them from doubting their abilities or feeling a sense of shame for what they have done. Firm consistent limits, patience, and support allow toddlers to develop socially acceptable behaviour and cope with the frustration of learning self-control (Santrock, 2007).

Socially, toddlers remain strongly attached to their parents and fear separation from them. In their parents' presence, toddlers feel safe, and their curiosity is evident in their exploration of the environment. Children continue to engage in solitary play during toddlerhood but also begin to participate in parallel play, which is playing beside rather than with another child. Toddlers who are just learning what belongs to them are often possessive of their toys. They learn the joy of sharing when they offer parents or caregivers toys to hold and the parents or caregivers express pleasure.

Health Risks

Their newly developed locomotion abilities and insatiable curiosity put toddlers at risk for injury. Toddlers need close supervision at all times, particularly when in environments that have not been child-proofed (Figure 22-5). Creating a safe, childproof environment in the home is essential for preventing accidental injuries.

Poisonings occur frequently in children nearing 2 years of age because they are interested in placing any object or substance in their mouths to learn about it. Parents must remove or lock up all possible poisons, including plants, cleaning materials, and medications. Lead poisoning can pose a health hazard for younger children (Leitch, 2007). Health care

Figure 22-5 Safety precautions should be provided for toddlers.
Source: Courtesy Elaine Polan, RNC, BSN, MS.

providers need to educate families living in older homes about the risks, screening, and treatment of lead poisoning. Because of toddlers' lack of awareness regarding the danger of water and their newly developed walking skills, drowning is a major cause of accidental death in this age group. Toddlers can easily become separated from a parent because they often wander away. It is important to closely supervise toddlers, especially in an open public space. Setting limits is extremely important for toddlers' safety. In automobiles, toddlers must remain in car seats. Under Canadian law, infants up to 9 kg must ride in rear-facing car seats, but it is safer for children to remain in this position until they grow out of these seats (Transport Canada, 2011). The American Academy of Pediatrics (2011a) recommends rear-facing car seats for all children under the age of two. Children often learn to release the car restraints, and parents must be firm in their resolve not to drive unless the children are securely restrained. Toddlers depend completely on their parents for physical safety. Health care providers must educate parents on proper use of child passenger restraints. Table 22-4 identifies developmental abilities acquired during this age period and injury prevention strategies.

Health Concerns

Nutrition. Most toddlers stop drinking breast milk or formula and begin drinking cow's milk. Nutritional requirements are increasingly met by solid foods. Because the consumption of more than 1 L of milk per day usually decreases children's appetite for these essential solid foods and results in inadequate iron intake, you should advise parents to limit milk intake to between 500 and 750 mL (two to three servings) per day. Children should not drink low-fat or skim milk until 2 years of age because they need the fat in whole milk for physical and intellectual growth. Healthy toddlers require a balanced daily intake of bread and grains, vegetables, fruit, dairy products, and proteins (see Chapter 42). Because parents frequently overestimate the size of a normal serving for their child, you should discuss normal serving sizes with parents.

Special dietary considerations are required for children who are ill, are undergoing surgery, or have conditions involving ingestion, absorption, or use of nutrients. Alterations in the type of foods and caloric requirements may be necessary. Strict vegetarian diets for children also require careful planning to ensure adequate, balanced protein intake. Regardless of children's health status, several basic principles of nutrition apply. Mealtime has psychosocial and physical significance. If the parents struggle to control toddlers' dietary intake, problematic behaviour and conflicts may result. Toddlers often develop "food jags," or the desire to eat one food repeatedly. Rather than becoming disturbed by this behaviour, parents should be encouraged to offer a variety of nutritious foods at meals and to provide only nutritious snacks between meals. Serving finger foods to toddlers allows them to eat by themselves and to satisfy their need for independence and control. Small, reasonable servings allow toddlers to eat all of their meals.

Preschooler

The **preschool period** encompasses the years between three and five years of age. Children refine the mastery of their bodies and often are eager to begin school. Many people consider these the most intriguing years of parenting because children exhibit positive emotions and can more effectively share their thoughts, interact, and communicate. Physical

development occurs at a slower pace than does cognitive and psychosocial development.

Physical Changes

Physical development continues in the preschool years. Heart and respiratory rates range from 60 to 100 beats and 23 to 25 breaths per minute, respectively. Blood pressure rises slightly to an average of 92/56 mm Hg. Children gain about 2.27 kg per year; the average weight is 14.5 kg at 3 years, 16.8 kg at 4 years, and about 18.6 kg at 5 years. Preschoolers grow 6 to 7.5 cm per year, double their birth length at about 4 years of age, and stand an average of 1 m tall by their fifth birthday. The elongation of the legs results in a more slender appearance. Little difference exists between the sexes, although boys are slightly larger with more muscle and less fatty tissue.

Large and fine muscle coordination improves. Preschoolers run well, walk up and down steps with ease, and learn to hop. By age 5 years, they can usually skip on alternate feet, can jump rope, and begin to skate and swim. Improvements in fine motor skills allow intricate manipulations. Children learn to copy crosses and squares. Triangles and diamonds are usually mastered between ages 5 and 6 years. Scribbling and drawing help children develop fine muscle skills and eye-hand coordination needed for the printing of letters and numbers.

Children need opportunities to learn and practise new physical skills. Early intervention programs are helpful in developing these skills, especially among disadvantaged children. Nursing care of healthy and ill children includes assessment of the availability of these opportunities. Although children with acute illnesses benefit from rest and exclusion from usual daily activities, children who have chronic conditions or have been hospitalized for long periods need ongoing exposure to developmental opportunities. With the parents, weave these opportunities into the children's daily experiences depending on their abilities, needs, and energy level.

Cognitive Changes

Preschoolers continue to master the preoperational stage of cognition. The first phase of this period, known as *preconceptual thought* (2 to 4 years), is characterized by perception-bound thinking, in that children judge people, objects, and events by their outward appearance or what seems to be true (Piaget, 1952). For example, a child may think that a 240 mL glass full of fluid contains more than a 300 mL glass that also contains 240 mL of fluid because the smaller glass appears fuller. Even if they watch the fluid from the smaller glass being poured into the larger glass and the smaller glass refilled, they still assert that the full, smaller glass contains more.

Children's thinking is hindered by their limited attention and attending skills. **Artificialism**, the misconception that everything in the world has been created by humanity, may result in children's asking questions such as "Who built the mountains?" Another misconception of preschool thinking, **animism**, the attribution of animal life to inanimate objects, often results in statements such as "Trees cry when their branches are broken." A third misconception is a type of reasoning called **immanent justice**, the notion that if a built-in code of law and order is broken, punishment will occur immediately (Santrock, 2007). For example, a child might think that he became sick because he lied to his mother.

At about the age of 4 years, the intuitive phase of preoperational thought develops. Children's ability to think more complexly is demonstrated by their ability to classify objects

TABLE 22-4 Injury Prevention for Toddlers and Preschoolers**Developmental Abilities Related to Risk of Injury**

Walks, runs, and climbs
 Is able to open doors and gates
 Can ride tricycle
 Can throw ball and other objects

Injury Prevention**Motor Vehicles**

Continue to use federally approved car restraint. Until the age of 2, children should ride in rear-facing car seats. Then, toddlers weighing up to 18 kg should be placed in a forward-facing child seat that is anchored to the vehicle frame with a tether strap. A child weighing 18 to 36 kg should be seated in a booster seat.
 Supervise child while he or she is playing outside, to prevent child from entering street.
 Do not allow child to play on curb or behind a parked car.
 Do not permit child to play in pile of leaves, snow, or anywhere that he or she is not visible.
 Supervise tricycle riding.
 Supervise child playing outside.
 Teach children to obey pedestrian safety rules.
 Supervise child when near traffic.

Has great curiosity
 Is helpless in water, unaware of its danger at any depth

Drowning

Supervise closely when child is near any source of water, including buckets. Keep bathroom doors and lid on toilet closed. Have fence around swimming pool, and lock gate. Teach the child swimming and water safety (and continue to protect him or her from injury).

Is able to reach heights by climbing, stretching, standing on toes, and using objects as a ladder
 Pulls objects
 Explores any holes or openings
 Can open drawers and closets
 Is unaware of potential sources of heat or fire
 Plays with mechanical objects

Burns

Turn pot handles toward back of stove.
 Place electric appliances, such as coffeemaker or frying pan, toward back of counter.
 Place guard rails in front of radiators, fireplaces, and heating appliances.
 Store matches and cigarette lighters in locked or inaccessible area; discard carefully.
 Place burning candles, incense, hot foods, ashes, embers, and cigarettes out of reach.
 Do not let tablecloth hang within child's reach.
 Do not let electric cord from iron or other appliance hang within child's reach.
 Cover electrical outlets with protective devices.
 Keep electrical wires hidden or out of reach.
 Do not allow child to play with electrical appliance, wires, or lighters.
 Stress danger of open flames; teach child what "hot" means.
 Always check bath water temperature; adjust hot-water heater temperature to 49°C or lower; do not allow child to play with faucets.
 Apply a sunscreen with SPF 15 or higher when child is exposed to sunlight.

Explores by putting objects in mouth
 Can open drawers, closets, and most containers
 Climbs
 Cannot understand warning labels

Poisoning

Place all potentially toxic agents (including plants) in a locked cabinet or out of reach.
 Put away medications and poisonous substances immediately after use; position (and tighten) child-resistant caps properly.
 Refer to medications as "drugs," not as "candy."
 Do not store large amounts of toxic agents.
 Promptly discard empty poison containers; never reuse such containers to store a food item or other poison.
 Teach child not to play in trash containers.
 Never remove labels from containers of toxic substances.
 Know number and location of nearest poison control centre (usually listed at beginning of telephone directories).

► **TABLE 22-4** Injury Prevention for Toddlers and Preschoolers—cont'd

Developmental Abilities Related to Risk of Injury

Is able to open doors and some windows
Goes up and down stairs
Has unrefined depth perception

Injury Prevention

Falls

Keep screen in window, nail securely, and install guard rail.
Place gates at top and bottom of stairs.
Keep doors locked or use child-resistant doorknob covers at entry to stairs, high porch, or other elevated area, such as laundry chute.
Remove unsecured or scatter rugs.
Apply nonskid mat in bathtub or shower.
Keep crib rails fully raised and mattress at lowest level.
Place carpeting under crib and in bathroom.
Keep large toys and bumper pads out of crib or playpen (child can use these as "stairs" to climb out).
Move child to youth bed when he or she is able to climb out of crib.
Dress child in safe clothing (soles that do not "catch" on floor, tied shoelaces, pant legs that do not hang on floor).
Never leave child unattended in shopping cart or stroller.
Supervise child at playgrounds; select play areas with soft ground cover and safe equipment.

Puts things in mouth
May swallow hard or nonedible pieces of food

Choking and Suffocation

Do not give child large, round chunks of meat, such as whole hot dogs (instead, slice into thin pieces).
Do not give child fruit with pits, fish with bones, dried beans, hard candy, chewing gum, nuts, popcorn, grapes, or marshmallows.
Choose large, sturdy toys without sharp edges or small removable parts.
Discard unused refrigerators, unused ovens, and other unused appliances; if storing old appliance, remove doors.
Keep automatic garage door opener in inaccessible place.
Select safe toy boxes or chests without heavy, hinged lids.
Keep window blind strings out of child's reach.
Remove drawstrings from clothing.

Is still clumsy in many activities
Is easily distracted from tasks
Is unaware of potential danger from strangers or other people

Bodily Damage

Avoid giving child sharp or pointed objects—such as knives, scissors, or toothpicks—especially when child is walking or running.
Do not allow lollipops or similar objects in the child's mouth when he or she is walking or running.
Teach safety precautions (e.g., to hold fork or scissors with pointed end away from face).
Store all dangerous tools, garden equipment, and firearms in locked cabinet.
Be alert to danger of animals, including household pets.
Use safety glass and decals on large glass areas, such as sliding glass doors.
Teach personal safety.
Teach child his or her name, address, and phone number, and teach child to ask for help from appropriate people (cashier, security guard, police officer) if lost; have identification on child (sewn in clothes, inside shoe).
Avoid dressing child in personalized clothing in public places.
Teach child to never go anywhere with a stranger.
Teach child to tell parents if anyone makes child feel uncomfortable in any way.
Always listen to child's concerns regarding others' behaviour.
Teach child to say no when confronted with uncomfortable situations.

Adapted from Hockenberry, M. J., & Wilson, D. (2011). *Wong's nursing care of infants and children* (8th ed., pp. 576–604). St Louis, MO: Mosby.

according to size or colour and by questions such as “Why do they call it the 31st day of the month instead of the 30 last?” Egocentricity persists, but during these 3 years, it begins to be replaced with social interaction; for example, a 5-year-old child offers a bandage to a child with a cut finger. Children become aware of cause-and-effect relationships, as illustrated by the statement “The sun sets because people want to go to bed.” Early causal thinking is also evident in preschoolers’ transductive thoughts (reasoning occurs from one particular to another). If two events are related in time or space, children link them in a causal manner. A hospitalized child, for example, may reason, “I cried last night, and that’s why the nurse gave me the shot.” As children near the age of 5 years, they begin to use or can be taught to use rules to understand causation. They then begin to reason from the general to the particular. This development forms the basis for more formal logical thought. The hospitalized child now reasons, “I get a shot twice a day, and that’s why I got one last night.”

Preschoolers’ knowledge of the world remains closely linked to concrete (perceived by the senses) experiences. Even their rich fantasy life is grounded in the perception of reality. The mixing of the two aspects can lead to many childhood fears, and adults may misinterpret children’s stories as lying when children are actually presenting reality from their perspective.

The greatest fear of this age group appears to be that of bodily harm, and it can be seen in children’s fear of the dark, thunderstorms, and medical personnel. This fear often makes children unwilling to allow nursing interventions such as measurement of vital signs. Preschoolers may cooperate if they are allowed to help you measure the blood pressure of a doll or teddy bear or if they are allowed to handle the equipment you will use.

Preschoolers’ moral development expands to include a beginning understanding of behaviours considered socially right or wrong. Children continue to be motivated, however, by the wish to avoid punishment and the desire to obtain a reward. The primary difference between this stage of moral development and that of toddlers is that preschoolers are better able to identify behaviours that elicit rewards or punishment and begin to label these behaviours as right or wrong.

Language. Preschoolers’ vocabularies continue to increase rapidly, and by the age of 6 years, children know more than 2100 words and can construct sentences containing 5 to 6 words (Hockenberry & Wilson, 2011). Language is more social, and questions expand to “Why?” and “How come?” Phonetically similar words such as “die” and “dye” or “wood” and “would” might cause confusion in preschool children. Avoid such words when you prepare children for procedures, and assess their comprehension of explanations.

Psychosocial Changes

The world of preschoolers expands beyond the family into the neighbourhood, where children meet other children and adults. Their curiosity and developing initiative lead to the active exploration of the environment, the development of new skills, and the making of new friends. Preschoolers have much energy, which enables them to plan and attempt many activities that may be beyond their capabilities, such as pouring milk into their cereal bowls. Guilt arises within children when they overstep the limits of their abilities and feel they have not behaved correctly. Children who in anger have wished their sibling were dead experience guilt if that sibling becomes ill.

Children need to be taught that “wishing” for something to happen does not make it occur. Parents should allow preschoolers to perform tasks on their own but must set firm limits and provide guidance.

During times of stress or illness, preschoolers may revert to bed-wetting or thumb-sucking and want the parents to feed, dress, and hold them. These dependent behaviours are often confusing and embarrassing to parents, who can benefit from your reassurance that they are the children’s normal coping behaviours. You should provide experiences that these children can master. Such successes help children return to their prior level of independent functioning. As language skills develop, children should be encouraged to talk about their feelings. Play is also an excellent way for preschoolers to vent frustration or anger and is a socially acceptable way to deal with stress.

Play. Children become more social after their third birthday as they shift from parallel to associative play. Children playing together engage in similar if not identical activity; however, no division of labour or rigid organization or rules exist. Most three-year-old children are able to play with one other child in a cooperative manner in which they make something or play designated roles, such as mother and baby. By the age of four years, children play in groups of two or three, and by five years, the group has a temporary leader for each activity.

In many play activities, preschoolers display awareness of social context. Sex role identification is strengthening and children most often assume roles of people of their own sex. Children frequently mimic or repeat social experiences. This tendency is especially significant in hospitalized children. Through play, children may express questions, fears, anger, and misunderstanding about their illnesses and care. Be alert to such clues and ensure that children can play within energy limits. Play can provide a healthy outlet for frustration, especially when children have been subjected to painful or restrictive experiences against their will.

Imaginary play depends on children’s memory of things they have seen or heard. This sociodramatic play involving other children occupies about a third of five-year-old children’s playtime. Pretending allows children to learn to understand others’ points of view, develop skills in solving social problems, and become more creative. Some children have imaginary playmates, which are a sign of creativity and healthy development.

Health Risks

As fine and gross motor skills develop, children become more coordinated with better balance; nevertheless, falls and other accidents remain a leading cause of injury. Guidelines for injury prevention in toddlers also apply to preschoolers (see Table 22-4). You should alert parents of children in this age group to the risks of poisoning and pedestrian–motor vehicle accidents. The leading cause of death in Canadian children is unintentional injury. All of these injuries are preventable. Children should be taught about safety in the home, and this teaching should be reinforced early in elementary school.

Health Concerns

Nutrition. Nutrition requirements for preschoolers vary little from those for toddlers. The average daily intake is 1800 calories. Parents may nonetheless worry about the amount of food their child is consuming. In most situations, however, the quality of the food is more important than quantity.

Preschoolers consume about half of the average adult portions. Finicky eating habits are characteristic of four-year-olds; in contrast, five-year-olds are more interested in trying new foods. It is important to monitor children's food intake because obesity may be evident first in preschool years (Leitch, 2007).

Sleep. Preschoolers average 12 hours of sleep a night and take infrequent naps. Sleep disturbances are common during these years. Disturbances may range from trouble getting to sleep to nightmares to prolonging bedtime with extensive rituals. Many preschoolers have had an overabundance of activity and stimulation during the day. Having children follow a set routine before bedtime helps them prepare for sleep.

Vision. Preschoolers should routinely be screened for vision problems. One of the common problems in the preschool period is amblyopia (blindness from disuse of an eye if a child has untreated strabismus). Early detection and treatment can improve vision for most children (Hockenberry & Wilson, 2011).

School-Age Children and Adolescents

School-age children and adolescents lead demanding, challenging lives. The changes that occur between 6 and 19 years of age are diverse and span all areas of growth and development. Physical, psychosocial, cognitive, and moral skills are developed, expanded, refined, and synchronized. The environment in which the individual develops skills also expands and diversifies. Instead of only family and close friends, the environment now may include the school, community, and religious institution. Because of expectations for development, increasing skill and knowledge base, and environmental expansion, the individual experiences new difficulties and dilemmas. With age-specific assessment, review the appropriate developmental expectations for each age group. For example, before assessing risk-taking behaviours, recognize that adolescents normally strive to achieve a sense of identity while developing a moral code compatible with society.

Direct school-age children and adolescents toward normal developmental behaviours, assisting them in improving their abilities and using them to cope. Table 22-5 provides an overview of developmental behaviours typical of school-age children and adolescents. You must also increasingly involve children or adolescents in charting a developmental course. Not only can they describe their feelings about the changes, but also they can think through these changes. Problem solving becomes more purposeful and sophisticated and results in the achievement of the outcomes that they desire. This paced, active participation may initiate a style of involvement in life-long self-care.

School-age children and adolescents must cope with many changes, and these can be a source of stress for children. For example, six-year-old children beginning school are confronted with new authority figures, teachers, and rules and restrictions. They need to work and play cooperatively with a large group of children of various cultural backgrounds. School-age children must meet the challenge of developing cognitive skills that enhance their reasoning and allow them to learn to read, write, and manipulate numbers. Because of the stress of these changes, children may develop physical and psychosocial health problems (e.g., increased susceptibility to upper respiratory infections, inadequate peer relationships, or poor performance in school). Design health promotion interventions that are based on an individual child's developmental stage.

School-Age Child

During these "middle years" of childhood, the foundation for adult roles in work, recreation, and social interaction is laid. In industrialized countries, this period begins when children start formal schooling at about the age of 6 years. **Puberty**, which occurs at about 12 years of age, signals the end of middle childhood. Great developmental strides are made during these years as children develop competencies in physical, cognitive, and psychosocial skills.

The school or educational experience expands children's world and is a transition from a life of relatively free play to a life of structured play, learning, and work. The school and home influence growth and development, necessitating adjustment by parents and children. Children must learn to cope with rules and expectations presented by the school and peers. Parents must learn to allow their children to make decisions, accept responsibility, and learn from life's experiences.

Physical Changes

The rate of growth during these early school years is slower than at any time since birth, but continues steadily. A particular child may not follow the pattern precisely. School-age children appear slimmer than preschoolers as a result of changes in fat distribution and thickness (Edelman & Mandle, 2010). Growth accelerates at different times for different children. The average increase in height is 5 cm per year, and weight, which is more variable, increases by 2 to 3 kg per year. An average 6-year-old is 116 cm tall and weighs 21 kg; the average 12-year-old is 150 cm tall and weighs 40 kg. Many children double their weight during these middle childhood years (Hockenberry & Wilson, 2011).

School provides children with the opportunity to compare themselves with children of the same age. The physical examination is an excellent opportunity to discuss with a child and parents the influences of genetic endowment, nutrition, and exercise on height and weight. Annual measurement of height and weight may reveal alterations in growth that are symptoms of the onset of a variety of childhood diseases.

Boys are slightly taller and heavier than girls during these early school years. Approximately two years before puberty, children experience a rapid acceleration in skeletal growth. Girls, who generally reach puberty first, begin to surpass boys in height and weight, which causes embarrassment to both sexes. In North America, puberty occurs between the ages of 9 and 13 years in girls and 11 and 14 years in boys.

Cardiovascular functioning is refined and stabilized during the school years. The heart rate averages 75 to 100 beats per minute, the blood pressure normalizes to approximately 110/65 mm Hg, and the respiratory rate stabilizes to 20 to 30 breaths per minute. Lung growth is minimal, and respirations become slower, deeper, and more regular. However, by the end of this period, the heart is six times the size it was at birth and has generally reached its adult size.

School-age children become more graceful during the school years because their large-muscle coordination improves and their strength doubles. Most children practise the basic gross motor skills of running, jumping, balancing, throwing, and catching during play, which results in refinement of neuromuscular function and skills. Fine motor skills improve, and as control is gained over fingers and wrists, children become proficient in a wide range of activities, although much individual difference exists in the rate and degree of proficiency.

► **TABLE 22-5** Developmental Behaviours of School-Age Children and Adolescents**School-Age Children****Relationships With Parents**

Children gradually learn that parents are less than perfect; children can become disillusioned with parents and wish that friends' parents were their own. They still rely on parents for unconditional love, security, guidance, and nurturing.

Relationships With Siblings

Siblings seem to be at odds with one another at home, and yet they tend to be each other's best defenders away from home. Younger children often idolize older siblings, and this frequently leads to competition. Older children may envy attention that younger siblings require and can be quite bossy and somewhat abusive.

Relationships With Peers

During primary grades (6–7 years), children of both sexes play together, depending on who is available and interested. Around age 8, social groupings of same-sex peers form. These groups allow children to declare their independence from parental rules and establish their own rules of membership and behaviour. Preadolescent (ages 10–12 years) friendships are characterized by having a best friend of the same sex. These relationships may be transient, but they are intense and allow discussion of all areas of life. Childhood "crushes" are common.

Self-Concept

Children's feelings of competence regarding mastery of tasks are key elements in forming self-esteem. Children need to receive positive feedback regarding their efforts. It is important for children to develop skills in at least one area such as reading, music, or swimming.

Fears

Fears related to body safety decline. Fears of supernatural beings such as ghosts and witches persist and decline slowly. New fears related to school and family occur. Children fear ridicule from teachers and friends and disapproval and rejection of parents. They also become frightened about death and events that they hear on the news, such as war and destruction of the environment.

Coping Patterns

To deal with stress, school-age children use problem solving and defence mechanisms such as denial and aggression. Several categories of coping behaviours of hospitalized school-aged children are inactivity (total silence, lack of activity, and apathy), orientation or precoping (looking and listening, walking around and exploring, and asking questions), cooperation (compliance with care), resistance (attempt to get away from the situation by turning away or making physical or verbal attacks), and controlling (assuming responsibility for self-care and suggesting how things could be done).

Morals

Children learn rules from parents, but their understanding of rules or reasons for them is limited until about age 10 years. Before that, they are concerned with their own needs first and may cheat to win games. After 10 years of age, they advocate justice and believe that punishment should fit the crime (e.g., if children break something, they should pay to have it fixed).

Adolescents

Adolescents desire increasing independence and autonomy and yet continue needing some dependence and limit setting by parents; this conflict places strain on the parent–child relationship. Effective communication and democratic parenting are the best tools for meeting this challenge.

Younger siblings rarely understand their adolescent siblings' need for privacy. Adolescents often enjoy interacting with and guiding younger brothers and sisters when timing is convenient for them and they can remain in control.

Peer group is of critical influence on adolescents, who increasingly need recognition and acceptance. Companionship offered by peer groups provides a secure environment for individuals to try out new ideas and share similar feelings and attitudes. Adolescents often form cliques with peers with similar interests from the same socioeconomic group. Cliques, which are highly exclusive, help their members develop their identities.

Formal and informal peer groups are a primary force in shaping self-concept of group members. Popularity and recognition within the peer group enhance self-esteem and reinforce self-concept. Total immersion in the peer group may make it appear that adolescents have no original thoughts and are incapable of making decisions. Adolescents who withdraw from peers into isolation struggle with developing identity.

Fears in this age group centre on peer group acceptance, body changes, loss of self-control, and emerging sexual urges. Adolescents constantly examine their bodies for changes and signs of imperfection. Any defect, real or imagined, is a cause of endless worry.

Coping behaviours expand with experiences adolescents have gained from life and from developing cognitive maturity. By age 15, most adolescents use a full range of defence mechanisms, including rationalization and intellectualization. Adolescents' problem-solving abilities have matured, and they can reason through philosophical discussions and complex situations that require abstract thinking and proposition of hypotheses. Some adolescents use avoidance coping strategies in which a problem is denied or repressed and an attempt is made to reduce tension by engaging in substance abuse or avoiding people.

According to Kohlberg (1964), as youths approach adolescence, they reach conventional level, where internalization of expectations of their family and society begins. Initially, youths exhibit considerable conformity to rules to win praise or approval from others and to avoid social disapproval or rejection; later, they seek to avoid criticism from people of authority in institutions.

► TABLE 22-5 Developmental Behaviours of School-Age Children and Adolescents—cont'd

School-Age Children**Diversional Activities**

School-age children play cooperatively in group activities such as sports and jumping rope. Play becomes competitive, and children often have difficulty learning to accept losing. Teasing, insults, dares, superstitions, and increased sensitivity are characteristics of this age.

Nutrition

Children have definite likes and dislikes. Few nutritional deficiencies occur in this age group. Children have voracious appetites after school and need quality snacks such as fruit and sandwiches to avoid empty-calorie foods such as chips and candy.

Adolescents

Many teenagers develop special interests in certain sports and concentrate on developing maximal skills therein. Recreational activities are often determined by what is popular with peers and what can provide independence from parents (e.g., computers, cars).

Total nutritional needs become greater during adolescence. Girls' caloric needs decrease and their need for protein increases slightly. Adolescents need to increase their consumption of iron-rich foods, and growth spurts increase calcium demand.

► TABLE 22-6 Average Motor Development in School-Age Children

Ages 6-7 Years**Fine Motor Skills**

Uses knife to butter bread and learns to cut tender meat
Cuts, folds, and pastes paper
Prints with pencil
Draws person with 12-16 details
Copies triangle at age 6 years and diamond by age 7 years
Colours within lines of picture
Needs assistance to clean teeth thoroughly

Ages 8-10 Years

Uses knife and fork simultaneously
Learns to thread needle and tie knot
Uses hammer, saw, and screwdriver
Becomes proficient at cursive writing
Uses symbols in drawing (e.g., bird, star)
Builds simple models of cars and planes and does simple handicrafts
Can learn to floss teeth effectively and be independent in tooth care

Ages 11-12 Years

Learns to peel apples and potatoes
Sews simple garments on machine
Builds simple objects like birdhouse
Enjoys writing in decorative script
Begins to use creative and artistic talents
Builds complex models of cars and planes and does complex handicrafts
Learns to play musical instrument
Becomes proficient in caring for teeth with braces and other appliances

Gross Motor Skills

Remains in constant motion when awake
Moves more cautiously at age 7 years than at age 6 years
Hops and jumps into small squares
Learns to roller skate, skip rope, ride a bicycle, and swim

Catches, throws, and hits a baseball
Engages in alternate rhythmic hopping
Engages in complex styles of skipping rope while reciting verbal jingles

Can perform standing broad jump of 1.5 m
Can perform standing high jump of 1 m
Engages in sports involving simultaneous use of two or more complex motor skills, such as ice skating, skateboarding, or playing hockey

Self-Care

Takes bath without supervision
Often returns to finger feeding
Learns to brush and comb hair in acceptable manner without help
Puts on most clothes but may need assistance with final adjustments

Learns to clean bathroom after bath
Enjoys fixing own snacks and sack lunch
Learns to part hair and insert barrettes
Dresses self completely and can help younger siblings with clothes
Can make own bed

Dusts, vacuums, and straightens own room
Learns to cook simply prepared foods
Washes, dries, and fixes own hair
Learns to sort, wash, dry, and press own clothing
Learns to care for fingernails and toenails

Most 6-year-olds can hold a pencil adeptly and print letters and words. By age 12 years, children can make detailed drawings and write sentences in script. Activities such as painting, drawing, playing computer games, and making models allow children to practise and improve newly refined skills. Parents should encourage children to pursue these activities. Table 22-6 describes specific gross motor and fine motor skills and their use in self-care activities.

The improved fine motor capabilities of school-age children allow them to become very independent in bathing, dressing, and taking care of other personal needs. They develop strong personal preferences in the way these needs are met. Illness and hospitalization threaten children's control in these areas; therefore, it is important to allow them to participate in care

and maintain as much independence as possible. For example, children whose care mandates restriction of fluids cannot be allowed to decide the amount of fluids they will drink in 24 hours, but they can help decide the type of fluids and can help keep a record of intake.

Assessment of neurological development is often based on fine motor coordination. This assessment may include penmanship, stacking ability, and performance of sequential, rapid, alternating movements such as touching the finger to the nose and then to the examiner's finger (smooth movement without tremors is the normal response). Fine motor coordination is crucial for academic success because children must be able to hold pencils and crayons, use scissors and rulers, and develop computer skills. The opportunity to practise these

skills through schoolwork and play is essential for the acquisition of coordinated, complex behaviours.

Other physical changes take place during the school years. Steady skeletal growth in the trunk and extremities occurs, and small- and long-bone ossification is present, but not complete by age 12 years. Dental growth is prominent during the school years. The first permanent or secondary teeth begin to erupt at approximately 6 years of age. Development of the permanent teeth has, however, been occurring for some time before eruption. The root of a primary tooth is absorbed, leaving the crown, which causes the tooth to become loose and fall out, making room for the permanent tooth. Eruption of secondary teeth usually begins with the 6-year molars, and the others follow the same order as with the primary teeth. By 12 years, all primary teeth have been shed, and the majority of permanent teeth have erupted. Infrequent or inadequate dental care remains a persistent problem for many children.

As skeletal growth progresses, body appearance and posture change. Earlier posture, which was characterized by a stoop-shouldered, slight lordosis and prominent abdomen, changes to a more erect posture. It is essential that children, especially girls after the age of 12 years, be evaluated for scoliosis, the lateral curvature of the spine.

Eye shape alters because of skeletal growth. This improves visual acuity, and normal adult 20/20 vision is achievable. Screening for vision and hearing problems is easier, and results are more reliable because school-age children can more fully understand and cooperate with the test directions. The public health nurse typically assesses the dental, visual, and auditory status of school-age children and refers those with possible deviations to their family practitioner or pediatrician.

Cognitive Changes

Cognitive changes provide school-age children with the ability to think in a logical manner and to understand the relationship between things and ideas (Hockenberry & Wilson, 2011). The thoughts of school-age children are no longer dominated by their perceptions, and thus their ability to understand the world greatly expands. At about seven years of age, children enter Piaget's (1952) third stage of cognitive development, known as **concrete operations**, in which they are able to use symbols to carry out operations (mental activities) in thought rather than in action. They begin to use logical thought processes with concrete materials (people, events, and objects they can touch and see).

Children in the concrete operational stage are considerably less egocentric than are younger children and develop the ability to concentrate on more than one aspect of a situation. School-age children now have the ability to recognize that the amount or quantity of a substance remains the same even when its shape or appearance changes. For instance, they can understand that two balls of clay of equal size retain the same amount of clay even when one is flattened and the other remains in ball shape.

The mental process of **classification** becomes more complex during the school years. Younger children can separate objects into groups according to shape or colour, whereas school-age children understand that the same element can exist in two classes at the same time. School-age children are becoming "thinkers" and are more capable of understanding another person's views and feelings (Santrock, 2007).

In middle childhood, youngsters can use their newly developed cognitive skills to solve problems. Some individuals are

better than others at problem solving because of intelligence level, education, and experience, but all children can improve these skills. Children who are good problem solvers demonstrate the following characteristics: a positive attitude that the problem can be solved with persistence, a concern for accuracy, the ability to divide the problem into parts for study, and the ability to avoid guessing while searching for facts. Adults can help children improve their problem-solving strategies by helping them define the problem, plan a solution, and then evaluate their solution. You can use these strategies to help hospitalized school-age children understand their illness and assume responsibility for their general health.

Language Development. Language growth is so rapid during middle childhood that these ages cannot be matched with language achievements. Children improve their use of language and expand their structural knowledge. They become more aware of the rules for linking words into phrases and sentences. They can also identify generalizations and exceptions to rules. They accept language as a means for representing the world in a subjective manner and realize that words have arbitrary, rather than absolute, meanings. They can use different words for the same object or concept, and they understand that a single word may have many meanings. Like younger children, school-age children watch parents and other adults to obtain clues about how to understand events (Santrock, 2007). Many school-age children use "bad language" to gain peer status and to shock adults. It often begins with bathroom language and progresses to sexual or genital words. Children begin to think about language, which enables them to appreciate jokes and riddles. Language acquisition is nurtured by social interactions with their parents and caretakers.

Psychosocial Changes

Erikson (1963) identified the developmental task for school-age children as industry versus inferiority (see Chapter 21). During this time, children strive to acquire competence and skills necessary for them to function as adults. School-age children who are positively recognized for success feel a sense of worth. Those faced with failure can feel a sense of unworthiness, which may result in withdrawal from school activities and peers.

Moral Development. The need for a moral code and social rules becomes more evident as school-age children's cognitive abilities and social experiences increase. For example, 12-year-old children are able to consider what society would be like without rules because of their ability to reason logically and their experiences with group play. They view rules as necessary principles of life, not just dictates from authorities. In the early school years, children strictly interpret and adhere to rules. As they grow older, their judgements become more flexible and they can evaluate rules for applicability to a given situation. School-age children consider motivations and behaviour when making judgements about the way their behaviours affect themselves and others. The abilities to be flexible when applying rules and to take the perspective of other people are essential in developing moral judgements. These abilities are present at times in earlier years but are more consistently displayed in later school years.

Peer Relationships. Group and personal achievements are important to school-age children. Success is important in physical and cognitive activities. Play involves peers and the pursuit of group goals. Although solitary activities are not eliminated, they are overshadowed by group play. Learning to

Figure 22-6 School-age children gain a sense of achievement by working and playing with peers. **Source:** Courtesy Elaine Polan, RNC, BSN, MS.

contribute, collaborate, and work cooperatively toward a common goal becomes a measure of success (Figure 22-6).

School-age children prefer same-sex peers to opposite-sex peers. In general, girls and boys view the opposite sex negatively. Peer influence becomes diverse during this stage of development. Conformity is evidenced in mannerisms, clothing styles, and speech patterns, which are reinforced and influenced by contact with peers. During this period, clubs and peer groups become prominent. Group identity increases as school-age children approach adolescence. Also, during the “tween” years (i.e., ages 8 to 12), children are increasingly exposed to social media. To help tweens and teens safely navigate the online social world, the American Academy of Pediatrics (2011b) recommends the following to parents:

- Learn about social media first-hand and monitor your child online.
- Require that you and your child “friend” each other.
- Speak to your child daily about his or her online habits.
- Place the home computer in a public room (e.g., family room).
- Emphasize that everything sent over the Internet and cell-phone can be shared with the whole world.
- Discourage children from gossiping, spreading rumours, or bullying.
- Set time limits for cellphone and Internet use.
- Be vigilant about warning signs of trouble, such as dropping grades, and skipping activities and homework for social media.
- Speak to your child about “sexting” in a manner that is appropriate to your child’s age.

Sexual Identity. Sigmund Freud described middle childhood as the latency period because he believed that children of this age had little interest in their sexuality. Today, many researchers believe that school-age children have a great deal of curiosity about their sexuality. Some may experiment, but this play is usually temporary. Children’s curiosity about adult magazines or meanings of sexually explicit words is also an example of their sexual interest. This is the time for children to have exposure to sex education, including information on sexual maturation, reproduction, and relationships (Edelman & Mandle, 2010).

Health Risks

Accidents and injuries are major health problems affecting school-age children. Motor vehicle accidents and accidents related to recreational activities or equipment are the leading causes of death or injury from the age of one year to adulthood (Edelman & Mandle, 2010). Unintentional injuries account for nearly half of all childhood deaths (Table 22-7).

Although falls account for a major portion of pediatric hospital admissions, they account for less than 5% of pediatric deaths resulting from injury. However, even though an accident may not result in death, it still can be a major cause of disability in children. More children die from automobile accidents than from all major preventable childhood diseases. The rates of injury and death have decreased since the institution of automobile child restraint laws.

School-age children are also significantly affected by respiratory illnesses, especially asthma, cancer, and heart disease (Hockenberry & Wilson, 2011). In this age group, these problems have a relatively low mortality rate, but a high morbidity rate in comparison with accidents. Cancers are the second leading cause of death in children 5 to 14 years of age (Hockenberry & Wilson, 2011). Leukemia is the most frequent type, and brain tumours and lymphoma are second and third, respectively.

Infections account for the majority of all childhood illnesses; respiratory infections are the most prevalent. The common cold remains the chief illness of childhood. Children living in poverty are more prone to disease and disability. Intellectual disabilities, learning disorders, sensory impairments, emotional difficulties, behavioural problems, and malnutrition are far more prevalent among children living in poverty (Campaign 2000, 2010).

Poverty and the prevalence of illness are highly correlated, probably because access to health promotion and preventive health care activities are minimal for children living in poverty. Poor nutrition and access to early intervention programs continue to be major health concerns for impoverished families. Education, social and health care reform, and environmental change are necessary to positively influence the health of children. Children’s developing cognitive and psychomotor skills make it possible for them to become more involved in health promotion and the management of chronic illness.

Health Concerns

During the school years, identity and self-concept become stronger and more individualized. School-age children are aware of their bodies and are sensitive about being exposed. Provide for privacy and offer explanations of common procedures. This approach helps foster children’s self-esteem and lessens their fear of pain and intrusion (Hockenberry & Wilson, 2011).

Health Education. The school years are crucial for the acquisition of behaviours and health practices for a healthy adult life. Because cognition is advancing during the period, effective health education must be developmentally appropriate. Promotion of good health practices is a nursing responsibility. A comprehensive school health approach includes programs, activities, and services that take place in schools and their surrounding communities in order to enable children and youth to improve their health and develop to their fullest potential (Canadian Association for School Health, 2007; Box 22-6).

► **TABLE 22-7** Injury Prevention for School-Age Children**Developmental Abilities
Related to Risk of Injury****Injury Prevention****Motor Vehicles**

Is increasingly involved in activities away from home
Is excited by speed and motion
Can be reasoned with
Does not always perceive injury risk
Is easily distracted by environment

Educate child regarding proper use of seat belts while a passenger in a vehicle.
Maintain discipline while a passenger in a vehicle (e.g., keep arms inside, do not lean against doors, do not interfere with driver).
Remind parents and children that no one should ride in the bed of a pickup truck.
Emphasize safe pedestrian behaviour.
Insist that child wears safety apparel (e.g., helmet) when applicable, such as when riding a bicycle or using a skateboard, all-terrain vehicle, or snow machine.

Drowning

Is apt to overdo activities
May work hard to perfect a skill
Is cautious but not fearful

Teach child to swim.
Teach basic rules of water safety.
Select safe and supervised places to swim.
Check sufficient water depth for diving.
Insist that child swims with a companion.
Use an approved flotation device in water or boat.
Learn cardiopulmonary resuscitation (CPR).

Burns

Demonstrates increasing independence
Enjoys trying new things

Make sure smoke detectors are in homes. Set hot water temperatures (49°C–54°C) to avoid scald burns.
Instruct child in behaviour in areas involving contact with potential burn hazards (e.g., gasoline, matches, bonfires or barbecues, lighter fluid, firecrackers, cigarette lighters, cooking utensils, chemistry sets).
Instruct child to avoid climbing or flying kites around high-tension wires.
Instruct child in proper behaviour in the event of fire (e.g., fire drills at home and school).
Teach child safe cooking (use low heat; avoid frying; be careful of steam burns, scalds, or exploding foods, especially in microwave ovens).
Teach children about the danger of fire, and instruct them that if their clothing is on fire, they should “stop,” “drop,” and “roll.”

Substance Abuse and Poisoning

May be easily influenced by peers
Has strong allegiance to friends

Educate child regarding hazards of taking nonprescription drugs and chemicals, including tobacco and alcohol.
Teach child to say no if he or she is offered illegal or dangerous drugs or alcohol.
Keep potentially dangerous products in properly labelled receptacles, preferably locked and out of child's reach.

Bodily Damage

Demonstrates increased physical skills
Needs strenuous physical activity
Is interested in acquiring new skills and perfecting attained skills
Is daring and adventurous, especially with peers
Frequently plays in hazardous places
Confidence often exceeds physical capacity
Desires group loyalty and has strong need for friends' approval
Attempts hazardous feats
Delights in physical activity
Is likely to overdo activity
Has growth in height that exceeds muscular growth and coordination

Help provide facilities for supervised activities.
Encourage playing in safe places.
Keep firearms safely locked up.
Teach proper care of, use of, and respect for devices with potential danger (e.g., power tools).
Teach children not to tease or surprise dogs, invade their territory, take dogs' toys, or interfere with dogs' feeding.
Teach safety regarding use of corrective devices (glasses); if child wears contact lenses, monitor duration of wear to prevent corneal damage.
Stress careful selection, use, and maintenance of sports and recreation equipment such as skateboards and in-line skates.
Emphasize proper conditioning, safe practices, and use of safety equipment for sports or recreational activities.
Caution against engaging in hazardous sports, such as those involving trampolines.
Use safety glass and decals on large glassed areas, such as sliding glass doors.
Use window guards to prevent falls.
Teach stranger safety.
Avoid personalized clothing in public places.
Caution child to never go anywhere with a stranger.
Have child tell parents if anyone makes child feel uncomfortable in any way.
Always listen to child's concerns regarding others' behaviour.
Teach child to say no when confronted with uncomfortable situations.
Help child avoid carrying more than 10%–15% of body weight in a backpack, and teach child to always put backpack on to evenly distribute weight; a light-weight backpack with wide shoulder straps, a waist strap, a padded back, and multiple compartments should be used.

► BOX 22-6

Critical Functions of Comprehensive School Health

A comprehensive approach to promoting health in schools includes the following:

- Promote healthy habits and illness prevention measures, with attention to multicultural, linguistic, physical, cognitive, and emotional factors.
- Intervene to assist children and youth who are in need or at risk.
- Help support children who are already experiencing poor health.
- Foster parental education on health issues.
- Identify learning disabilities early, and begin appropriate interventions to foster learning and self-esteem.
- Facilitate growth and self-actualization.
- Emphasize positive health attitudes.
- Foster positive life skills that enhance successful coping.
- Encourage physical activity.
- Encourage involvement of individuals, families, and communities as active partners in the health care of school-age children.

Adapted from Canadian Association for School Health. (2007). *Canadian consensus statement (Revised 2007): Comprehensive school health*. Retrieved from http://www.safehealthyschools.org/CSH_Consensus_Statement2007.pdf.

School-age children should receive age-appropriate sexual health education that begins before the onset of sexual activity (Kliegman et al., 2011). Other topic areas for elementary health education curricula include the promotion of adequate nutrition, oral hygiene, and regular health supervision. School-age children should also be educated about prevention of tobacco, drug, and alcohol use (Edelman & Mandle, 2010).

Instruct parents regarding health promotion appropriate for school-age children. Parents need to recognize the importance of annual checkups for immunizations, screenings, and dental care. When school-age children reach 10 years of age, it is recommended that their parents talk with the children about upcoming pubertal changes (Hockenberry & Wilson, 2011). Topics should include introductory information regarding menstruation, sexual intercourse, and reproduction. Provide age-appropriate written materials to aid parents in their efforts. The settings in which health promotion activities can occur are varied: the classroom, a school-based clinic, a community-based clinic, or community settings such as a public library or community centre.

Table 22-8 presents a list of possible health promotion topics for school-age children.

Safety. Because accidents are the leading cause of death and injury in school-age children, safety is a priority health teaching consideration. You can contribute to the general health of children by educating them about safety measures to prevent accidents. At this age, children should be encouraged to take responsibility for their own safety.

Nutrition. You can contribute to the promotion of healthy lifestyle habits, including nutrition. School-age children should participate in educational programs that enable them to plan, select, and prepare healthy meals and snacks. These foods should be consistent with the recommendations in *Canada's Food Guide* (Health Canada, 2007b), which include limiting intake of fats and increasing intake of complex carbohydrates, fruits, and vegetables. Box 22-7 outlines several learning activities appropriate for this age group. In addition, encourage daily physical activity for all children.

► TABLE 22-8

Health Promotion for School-Age Children**School-Age Health Concerns****Health Promotion Interventions**

Nutrition

Provide nutrition education that promotes healthy lifestyle: for example, limiting fat intake to 30% of calories, limiting saturated fat to 10% of calories, avoiding overeating.

Oral hygiene

Provide examples of low cariogenic snacks.
Review mechanics of dental hygiene: brushing, flossing.
Stress importance of biannual dental checkups.

Infections

Provide immunization information and follow-up.

Teach infection prevention practices (handwashing, care of minor skin injuries).

Teach concepts of viral and bacterial illness.

Promote handwashing and regular bathing.

Tobacco, alcohol, and drug use

Provide programs in preventing tobacco use.

Provide information regarding the hazards of alcohol and drug use.

Human sexuality

Provide information about sexual maturation and reproduction in age-appropriate manner.

Encourage parents to view their children's sexual curiosity as part of the developmental process.

Discuss with parents the learning needs of their children regarding sexuality.

Provide age-appropriate sexual health education.

► BOX 22-7

Interventions to Promote Education About Nutrition

Include healthy eating as part of the education programs at school.

- Make healthy foods available in school vending machines and at school sporting or other events.
- Encourage nutritious and nonfood items for school fundraising projects.
- Use positive messages to reinforce healthy eating and physical activity.
- Have teachers and school personnel model healthy eating habits.
- Limit access to unhealthy foods and beverages.
- Provide positive reinforcement for healthy food choices.
- Create a pleasant environment for eating.
- Promote safe food handling practices.
- Involve parents and the community in promoting healthy eating in schools.

Adapted from Knowledge Network. (n.d.). *Making it happen: Healthy eating at school*. Burnaby, BC: Author. Retrieved from <http://healthyeatingatschool.ca/>.

Growth may slow down during the school years in comparison with infancy and adolescence. Obesity is the most common nutritional problem during childhood. Obesity is believed to begin in utero and during infancy and childhood (Edelman & Mandle, 2010; Heindel, 2011). Obesity increases the risk for hypertension, diabetes, coronary heart disease, and psychosocial problems; some children with obesity have low self-esteem, poor body image, and reduced quality of life and interpersonal relationships (Sgenci & Faith, 2011). Obesity may occur because children often rush into the home after school or play and eat the most easily obtainable and appealing foods. Unfortunately, these foods are often high in calories and low in nutrition. Providing nutritious snacks is often the best way for a parent to ensure good nutritional intake. Caregivers should provide ready access to fresh fruit, raw vegetables, cheese, popcorn, and high-protein snacks such as skim-milk pudding and hot chocolate. Consider cultural, economic, and social issues when planning successful eating interventions (Edelman & Mandle, 2010).

Help families and children prevent obesity through proper nutrition and exercise. Many families often eat in fast-food restaurants in which the food is high in fat, calories, and salt. Encourage healthy food choices in these situations. Selections should include meats that are not breaded and are broiled, shakes that are made with low-fat yogurt or skim milk, and fruits and vegetables that are fresh or prepared in a low-calorie manner.

Adolescent

Adolescence is the period of development between childhood and adulthood, usually between 12 and 19 years of age. The term *adolescent* usually refers to psychological maturation of the individual, whereas *puberty* refers to the point at which reproduction becomes possible. The hormonal changes of puberty result in changes in the appearance of the young person: the primary sexual characteristic changes (maturation of the reproductive organs) and the secondary sexual characteristic changes (such as the development of pubic hair and female breasts). Mental development during puberty results in the ability to hypothesize and deal with abstractions. In addition, adolescents become much more social, and their behavioural patterns become much less predictable. Adjustments and adaptations are needed to cope with these simultaneous changes and the attempt to establish a mature sense of identity. Many people refer to adolescence as a stormy and stressful period filled with inner turmoil, but it is recognized that most teenagers successfully meet the challenges of this period. These challenges may cause adolescents to be moody and difficult. Within adolescence, three subphases exist: early adolescence, including puberty (ages 12 to 14 years), middle adolescence (ages 14 to 17 years), and late adolescence (ages 17 to 19 years). Opportunities, challenges, changes, skills, pressures, and physical, cognitive, and psychosocial development vary widely among the subphases (Table 22-9).

Your understanding of development provides a unique perspective for helping teenagers and parents anticipate and cope with the stresses of adolescence. Primary health care activities, particularly education, can promote healthy development. These activities occur in a variety of settings and can be directed at adolescents, parents, or both. For example, you can conduct seminars in a high school to provide practical suggestions for solving problems of concern to a large group

of students, such as treating acne or making responsible decisions about drugs or alcohol use. Similarly, a group education program for parents about how to cope with teenagers would promote parental understanding of adolescent development. These programs can be held in the school, clinic, private office, or community centre. To learn more about specific topics or problems, you need to identify teenagers' needs and desires. Involvement produces more active, interested learners.

Physical Changes

Physical changes occur rapidly in adolescence. Sexual maturation occurs with the development of primary and secondary sexual characteristics. Four main focuses of the physical changes are as follows:

- Increased growth rate of skeleton, muscle, and viscera
- Sex-specific changes, such as changes in shoulder and hip width
- Alteration in distribution of muscle and fat
- Development of the reproductive system and secondary sex characteristics

The timing of physical changes associated with puberty varies widely between sexes and within the same sex. Girls tend to begin their physical changes earlier than boys. Variations are more pronounced in boys (Kliegman et al., 2011). The sequence of pubertal growth changes is the same in most individuals (Table 22-10).

Changes are created by hormonal fluctuations within the body when the hypothalamus begins to produce gonadotropin-releasing hormones. This change sends the pituitary gland a signal to secrete gonadotropic hormones. Gonadotropic hormones stimulate ovarian cells to produce **estrogen** and testicular cells to produce **testosterone**. These hormones contribute to the development of secondary sex characteristics such as hair growth and voice changes and play an essential role in reproduction. The changing concentrations of these hormones are also linked to acne and body odour. Understanding these hormonal changes enables you to reassure adolescents and educate them about body care needs.

Boys who mature early have been shown by some researchers to be more poised, relaxed, good-natured, skilled in athletic activities, and likely to be school leaders than boys who mature late. In contrast, girls who mature early have been found to be less sociable and more shy and introverted, perhaps as a result of feeling conspicuous (Edelman & Mandle, 2010). Such girls are more conscious of body development, such as breast development, and thus stand out from many of their peers.

Being like their peers is extremely important for adolescents. You need to stress that normal sexual changes are quite variable. As with increases in height and weight, the pattern of sexual changes is more significant than their time of onset. Large deviations from normal patterns necessitate investigation.

Any deviation in the timing of the physical changes can be extremely difficult for adolescents to accept. Provide emotional support for those undergoing early or delayed puberty. Even adolescents whose physical changes are occurring at the normal times may seek reassurance about their normality.

Height and weight usually increase during the prepubertal growth spurt. The growth spurt for girls generally begins between 8 and 14 years of age. Height increases 5 to 20 cm, and weight increases by 7 to 25 kg. The growth spurt in boys usually occurs between 10 and 16 years of age. Height increases approximately 10 to 30 cm, and weight increases by 7 to 30 kg.

► **TABLE 22-9** Growth and Development During Adolescence

Early Adolescence (11-14 Years)	Middle Adolescence (15-17 Years)	Late Adolescence (18-20 Years)
Growth Rapidly accelerating growth reaches peak velocity. Secondary sex characteristics appear.	Growth decelerates in girls. Stature reaches 95% of adult height. Secondary sex characteristics are well advanced.	The body is physically mature. Structural and reproductive growth are almost complete.
Cognition The person explores newfound ability for limited abstract thought. The person experiences uncertainty when confronted with new values. One's "normality" is compared with that of peers of same sex.	Capacity for abstract thinking develops. Intellectual powers, often in idealistic terms, are increased. Concerns with philosophic, political, and social problems arise.	Abstract thought is established. The person can perceive and act on long-range options. The person is able to view problems comprehensively. Intellectual and functional identity are established.
Identity The person is preoccupied with rapid body changes. The person tries out various roles. Attractiveness is measured by acceptance or rejection by peers. Conformity to group norms is typical. Self-esteem declines.	Body image is modified. Person is very self-centred; narcissism is increased. Tendency toward inner experience and self-discovery develops. Fantasy life is rich. The person becomes idealistic. The person is able to perceive future implications of current behaviour and decisions; variable application.	Body image and gender role definition is nearly secured. Sexual identity is mature. Identity is consolidated. Self-esteem stabilizes. The person is comfortable with physical growth. Social roles are defined and articulated.
Relationships With Parents	Major conflicts over independence and control occur. This is the low point in parent-child relationship. The person makes the greatest push for emancipation and disengagement. Emotional detachment from parents is final and irreversible; mourning occurs.	Emotional and physical separation from parents is completed. Independence is achieved from family with less conflict. Emancipation is nearly secured.
Relationships With Peers	The person has a strong need for identity to affirm self-image. Behavioural standards are set by peer group. Acceptance by peers is extremely important; rejection is feared. The person explores ability to attract the opposite sex.	Peer group recedes in importance in favour of individual friendship. Male-female relationships are tested against possibility of permanent alliance. Relationships are characterized by giving and sharing.
Sexuality	Multiple plural relationships are characteristic. The person decisively turns toward heterosexuality, bisexuality, or homosexuality. "Self-appeal" is explored. Feeling of "being in love" is common. Relationships are tentatively established.	The person forms stable relationships and attachment to another person. Capacity for mutuality and reciprocity grows. Dating is common. The person may publicly identify herself or himself as gay, lesbian, or bisexual. Intimacy involves commitment rather than exploration and romanticism.

Continued

► **TABLE 22-9** Growth and Development During Adolescence—cont'd

Early Adolescence (11–14 Years)	Middle Adolescence (15–17 Years)	Late Adolescence (18–20 Years)
Psychological Health Wide mood swings occur. Intense daydreaming is characteristic. Anger is outwardly expressed with moodiness, temper outbursts, verbal insults, and name-calling.	Tendency toward inner experiences is exhibited; person becomes more introspective. The person tends to withdraw when upset or when feelings are hurt. Emotions vacillate in time and range. Feelings of inadequacy are common; asking for help is difficult.	The person experiences more constancy of emotion. Anger is more apt to be concealed.

► **TABLE 22-10**

Average Sequences of Physiological Changes in Adolescence

Characteristics	AGE RANGE (YEARS)	
	Girls	Boys
Beginning of skeletal growth spurt	8–14.5 (peak: 12)	10.5–16 (peak: 14)
Beginning of breast development	8–13	—
Enlargement of testes and scrotal sac	—	10–13.5
Appearance of straight, pigmented pubic hair, which gradually becomes curly	8–14	10–15
Early voice changes (cracks)	—	11–14.5
Enlargement of penis and prostate gland	—	11–14.5
Menarche	10–18 (average: 12.25)	—
Spermatogenesis (ejaculation of sperm)	—	11–17 (average: 13.5)
Ovulation and completion of breast development	14–18 (average: 15.52)	—
Appearance of downy facial hair	—	12–17
Appearance of axillary (underarm) hair and increased output of oil and sweat-producing glands, which may lead to acne	10–16	12–17
Widening and deepening of female pelvis, with deposition of subcutaneous fat that gives rounded appearance to body	10–18	—
Increase in shoulder width	—	11–21
Deepening of male voice, with appearance of coarse and pigmented facial hair and appearance of chest and axillary hair as well as other body hair becoming more prominent, such as that on forearms and legs	—	16–21

In both sexes, the final 20% to 25% of adult height and 50% of adult weight are attained during this time (Hockenberry & Wilson, 2011).

Girls attain 90% to 95% of their adult height by **menarche** (the onset of menstruation) and reach their full height by 16 to 17 years of age, whereas boys continue to grow taller until 18 to 20 years of age. Fat is redistributed into adult proportions as height and weight increase, and gradually the adolescent torso takes on an adult appearance. Despite individual and sex differences, growth follows a similar pattern for both sexes. Growth in the length of the extremities occurs earliest, making the hands and feet appear very large and the legs very long; the individual often appears awkward and clumsy. At the same time, the lower jaw and nose become longer and the forehead higher and wider as the baby face of childhood disappears. Next, the thighs widen; then the shoulders broaden, and growth of the trunk proceeds. The female hips widen and the male shoulders broaden throughout adolescence.

Personal growth curves help you assess physical development. The individual's sustained progression along the curve, however, is more important than a comparison of measurements with the norm. To evaluate changes, you should chart growth measurements during routine health assessments.

Adolescents are sensitive about physical changes that make them different from peers. For this reason, they are generally interested in the normal pattern of growth and in their personal growth curves. Therefore, you should share this information to reassure adolescents that their own patterns are normal.

Cognitive Changes

According to Piaget (1952), the changes that occur within the mind and the widening social environment of adolescents result in the highest level of intellectual development, known as **formal operations** (see Chapter 21). However, without an appropriate educational environment, some people may not attain this stage. Those who are guided toward rational thinking may reach this stage early.

Adolescents develop the ability to determine possibilities, rank possibilities, solve problems, and make decisions through logical operations. The teenager can deal effectively with hypothetical problems. When confronted with a problem, the teenager is able to consider an infinite variety of causes and solutions. Adolescents can move beyond the physical or concrete properties of a situation and use reasoning powers to understand the abstract. School-age children think about what is, whereas adolescents can imagine what might be. These

newly developed abilities allow the individual to have more insight and skill in playing video games, computer games, and board games that necessitate abstract thinking and deductive reasoning about many possible strategies. A teenager can solve problems by simultaneously manipulating several abstract concepts.

Development of the ability to reason abstractly is important in the pursuit of an identity. For example, newly acquired cognitive skills enable the teenager to define appropriate, effective, and comfortable sex role behaviours and consider their impact on peers, family, and society. The ability to think logically about these behaviours and their outcomes encourages adolescents to develop personal thoughts and means of expressing sexual identity. In addition, because their level of cognitive functioning is higher, adolescents are receptive to more detailed and diverse information about sexuality and sexual behaviours. For example, sex education can include an explanation of physiological sexual changes and birth control measures.

By middle adolescence, an introspective quality emerges. At this time, adolescents believe that they are unique. They also may believe, because of their new physical skills, that they are invulnerable, and so they engage in risk-taking behaviours: many state that they “can drive fast and not get into an accident.” Other typical adolescent behaviours include self-consciousness and the desire for privacy.

The complex development of thought during this period leads adolescents to question society and its values. Although adolescents have the capability to think as logically as adults, they do not yet have experiences from which to gain perspective. It is common for teenagers to consider their parents too narrow-minded or too materialistic. This perception can result in conflicts between teenagers and parents. Cognitive abilities and performance vary greatly among adolescents. In fact, an adolescent may perform at different levels in different situations on the basis of past experiences, formal education, and motivation in the use of logic and effective deductive reasoning.

Language Skills. Language development is fairly complete by adolescence, although vocabulary continues to expand. The primary focus becomes communication skills that can be used effectively in various situations. Adolescents need to communicate thoughts, feelings, and facts to others. The skills used in communication situations are varied. Adolescents must select the person with whom to communicate, decide on the message, and choose the way to transmit the message. For example, the way teenagers tell parents about failing grades is not the same as the way that they tell friends. Adolescents develop different skills and styles of communication and learn how and when to use them most effectively. These diverse communication skills are used and refined throughout life (Santrock, 2007). Good communication skills are crucial for overcoming peer pressure and unhealthy behaviours. The following are some hints for communicating with adolescents:

- Do not avoid discussing sensitive issues. Asking questions about sex, drugs, and school demonstrates your interest in their well-being and may open the channels for further discussion.
- Ask open-ended questions.
- Try to discern the meaning behind their words or actions.
- Be alert to clues to their emotional state.
- Involve other individuals and resources when necessary.

Psychosocial Changes

The search for personal identity is the major characteristic of adolescent psychosocial development. Teenagers must establish close peer relationships or risk remaining socially isolated. Erikson (1963) viewed identity (or role) confusion as the prime danger of this stage and suggested that the cliquishness and intolerance of differences seen in adolescent behaviour are defences against identity confusion (Erikson, 1968). Adolescents work at becoming emotionally independent from their parents, while retaining family ties. In addition, they need to develop their own ethical systems that are based on personal values. Choices about vocation, future education, and lifestyle must be made. The various components of identity evolve from these stages and compose a total adult personal identity that is unique to the individual. Indecisiveness and the inability to make an occupational choice are behaviours indicating the lack of resolution to certain developmental tasks.

Gender Identity. Achievement of gender identity is enhanced by the physical changes of puberty. According to Freud, these physiological changes of puberty stimulate the libido, the energy source that fuels the sex drive (see Chapter 21). This change is evidenced by teenagers’ interest in romantic relationships and by their practice of masturbation. The physical evidence of maturity encourages the development of masculine and feminine behaviours. If these physical changes involve deviations, the person has more difficulty developing a comfortable sexual identity. Adolescents depend on these physical clues because they want assurance of maleness or femaleness and because they do not wish to be different from peers.

Other influences on gender identity are cultural attitudes and expectations of sex role behaviour and available role models. The masculine and feminine behaviours that teenagers see affect the way that they express sexuality.

Group Identity. Adolescents seek a group identity because they need esteem and acceptance (Figure 22-7). Similarity in dress, speech, or both is common in teenage groups. Popularity is a major concern for teenagers. Peer groups provide adolescents with a sense of belonging, approval, and the opportunity to learn acceptable behaviour. Popularity with both opposite-sex and same-sex peers is important. The strong need for group identity seems to conflict at times with the search for personal identity. It is as though adolescents require close bonds with peers so that they can later achieve a sense of individuality.

Family Identity. The movement toward stronger peer relationships contrasts with adolescents’ movements away from parents. Although financial independence for adolescents is not the norm in Canadian society, many adolescents work part-time, using their income to bolster independence. When adolescents cannot have a part-time job because of studies, school-related activities, and other factors, parents can provide allowances for clothing and incidentals, which encourage adolescents to develop decision-making and budgeting skills.

Some adolescents and families have more difficulty during these years than others. Adolescents need to make choices, act independently, and experience the consequences of actions. This testing, however, is best done against the background of firm family support. The family needs to allow independence while providing a haven in which adolescents can contemplate actions. Families unable to provide this support complicate movement toward identity formation. Health care support of a family and an adolescent may be essential to their success.

Figure 22-7 Social interactions strengthen a teenager's group identity. **Source:** Courtesy Cindy Murray, RN, PhD.

Assist families in considering ways that are appropriate for them to foster the independence of their adolescent while maintaining family structure. Many of these discussions involve curfews, jobs, and participation in family chores. Emancipation from the immediate family is most successful when accomplished gradually and results in a balance between independence and family ties.

Vocational Identity. Selecting an occupation or a vocational direction in life is a goal for adolescents. Because of society's changing needs, adolescents must be future oriented when making these choices. However, adolescents do not know which jobs will be available and rewarding 10 or 20 years in the future, and selecting a career is thus a complicated task. You need to be supportive to the family during this process and help adolescents select courses of action that promote self-satisfaction, identity, and continued opportunity for growth.

Moral Identity. The development of moral judgement depends heavily on cognitive and communication skills and peer interaction. Although moral development begins in early childhood, it is consolidated in adolescence because of the presence of certain skills. Adolescents learn that rules are cooperative agreements that can be modified to fit the situation, rather than absolute. Adolescents learn to use their own judgement rather than to use the rules to avoid punishment as in earlier years. Kohlberg (1964) explained moral development in terms of stages (see Chapter 21). At the highest level, morality is derived from individual principles of conscience. Adolescents judge themselves by internalized ideals, which often leads to conflict between personal and group values. Group values become less significant in later adolescence.

Not all adolescents attain the same level of moral development; however, they generally advance through the stages of moral development, and the sequence of the stages is similar for all individuals, even though the time at achievement varies. Kohlberg's (1964) moral development theory focuses on justice based on reciprocity and equal respect. Adolescent girls have been found to be more likely to give caring responses to moral problems, whereas adolescent boys have been found to give more justice-oriented responses (Gilligan, 1982).

Health Identity. Healthy adolescents evaluate their own health according to feelings of well-being, ability to function normally, and absence of symptoms (Hockenberry & Wilson, 2011).

Interventions to improve health perception might, therefore, concentrate on the adolescent period. The rapid changes during this period make primary health care programs especially crucial. Adolescents try new roles, begin to stabilize their identity, and acquire values and behaviours from which their adult lifestyle will evolve.

Health Risks

Injuries. Injuries, including self-inflicted injuries and injuries caused by motor vehicle accidents and poisoning, are the leading causes of death in Canadian adolescents (Pan et al., 2007). Feelings of being indestructible lead to risk-taking behaviour. Many injuries are preceded by the use of alcohol (Hockenberry & Wilson, 2011). Youths continue to be both the victims and perpetrators of violence.

Suicide. Suicide is increasing as a cause of death in adolescents between 15 and 19 years of age. Depression and social isolation commonly precede a suicide attempt, but suicidal thoughts probably result from a combination of several factors (Box 22-8).

You must be able to identify the factors associated with adolescent suicide risk and precipitating events. In addition, you should be alert to the following warning signs, which often occur for at least a month before suicide is attempted:

- Deterioration in school performance
- Social withdrawal
- Loss of initiative
- Loneliness, sadness, and crying
- Appetite and sleep disturbances
- Verbalization of suicidal thought

Immediate referrals to mental health providers are needed when assessment findings suggest that adolescents may be considering suicide. Guidance can help them focus on the positive aspects of life and strengthen coping abilities.

Substance Abuse. Adolescents may believe that mood-altering substances create a sense of well-being or improve

► BOX 22-8 Factors Associated With Suicide

History

Previous suicide attempt
Suicide attempt by family member or friend
History of child maltreatment
Past psychiatric hospitalization
Death of a parent when child was young

Individual Factors

Hopelessness
Marked, persistent depression
Alcohol or drug abuse
Impulsiveness
Difficulty tolerating frustration
Feelings of self-hatred, excessive guilt, or humiliation
Thinking disorder (wishes to join a deceased person, hears voices telling to kill self)
Physical, behavioural, developmental, or body image problems (delayed puberty, chronic illness, disability, attention deficit-hyperactivity disorder, learning disorders)
Gender identity or sexual orientation concerns; being gay, lesbian, bisexual, or transgender in an unsupportive environment
Seeing self as totally helpless: a victim of fate
Needing to do things perfectly

Family Factors

Difficult home situation: long, bitter parent-child conflict
Hostile parents
Overt rejection by one or both parents
Divorce or separation of parents
Recent or impending move
Family breakup or loss of parent
Stress of unrealistically high parental expectations
Parental indifference with very low expectations

Social and Environmental Factors

Firearms in the home
Incarceration
Lack of effective social support system
Isolation
Suicide of someone known
Few social, vocational, educational opportunities

Adapted from Hockenberry, M. J., & Wilson, D. (2011). *Wong's nursing care of infants and children* (9th ed., p. 836). St Louis, MO: Mosby.

level of performance. All adolescents are at risk for experimental or recreational substance use, but those with dysfunctional families are more at risk for chronic use and physical dependency. Some adolescents believe that substance use makes them more mature. They further believe they will look and feel better with drug usage. Alcohol is the substance most commonly used, followed by cannabis. Other substances frequently abused by teenagers include steroids, which are used to enhance athletic performances. It is believed that the use of these products may increase the likelihood of using other illicit drugs (Canadian Centre on Substance Abuse, 2010). Tobacco use, although decreasing, continues to be a problem among adolescents.

Eating Disorders. The number of eating disorders is on the rise in adolescents, particularly girls, and knowledge of growth progression may be a way to discourage radical weight

reduction activities. If an adolescent's growth deviates radically from the usual pattern, further assessment is necessary to identify the cause. Areas to include in the assessment are past and present diet history, food records, eating habits, attitudes, health beliefs, and socioeconomic and psychosocial factors (Hockenberry & Wilson, 2011). Weight extremes resulting from excessive or inadequate caloric intake are common during the adolescent years. Allowing an adolescent to see when and how the weight curve changed can be a first step in identifying the problem and implementing dietary changes.

Although anorexia nervosa and bulimia are classified as separate eating disorders, manifestations of the two overlap (Varcarolis & Halter, 2010). Anorexia nervosa is considered a clinical syndrome with both physical and psychosocial components. The majority of patients are adolescents and young women. Attending a highly competitive high school and being from a professional, upper-middle-class family increase the risk for this disorder. People with anorexia nervosa have an intense fear of gaining weight and refuse to maintain body weight at the normal minimum for their age and height.

Bulimia nervosa is most identified with binge eating and behaviours to prevent weight gain, including self-induced vomiting, misuse of laxatives and other medications, fasting, and excessive exercise (Hockenberry & Wilson, 2011). Because adolescents rarely volunteer information about behaviours to prevent weight gain, it is important to take a thorough dietary history. Society's expectations for thinness may have a strong influence on the development of these disorders. Eating disorders are thought to be more common among girls, but it is important to note that boys may also suffer from these disorders. Causes of eating disorders are the same for girls and boys.

Obesity and Physical Inactivity. Overweight and obesity, together with a decrease in physical activity, are becoming serious public health problems in Canada. In adolescents aged 12 to 17 years, rates of overweight have doubled and rates of obesity have tripled since the 1990s (Leitch, 2007). A contributing factor is a lack of physical activity; children and adolescents spend more time watching television and using computers, especially engaging in playing computer games. Parents and other people working with adolescents must encourage greater physical activity among this age group, must monitor computer use, and must promote healthy nutrition.

Sexual Experimentation. Sexual experimentation is common among adolescents. Peer pressure, physiological and emotional changes, and societal expectations contribute to early heterosexual and homosexual relations. Two prominent consequences of adolescent sexual activity are sexually transmitted infections and pregnancy (Hockenberry & Wilson, 2011).

Sexually Transmitted Infections. The incidence of sexually transmitted infections (STIs) reported is increasing in adolescents (Public Health Agency of Canada, 2008). Therefore, sexually active adolescents must be screened for STIs, even when they have no symptoms, because STIs can be asymptomatic. The annual physical examination of a sexually active adolescent should include a thorough sexual and genitourinary history and a careful examination of the genitalia so that genital warts, herpes, and other STIs are not missed. Recommended tests for women include Papanicolaou (Pap) smears, cervical cultures for gonorrhea and *Chlamydia* species, and syphilis tests; for men, urethral cultures for gonorrhea and

Chlamydia species and syphilis tests are recommended. If men have participated in homosexual activities, rectal and pharyngeal cultures also need to be taken to check for gonorrhea. Because the human papillomavirus (HPV) is a common STI, all Canadian provinces and territories have HPV vaccine programs, whereby adolescent girls are given a vaccine that is effective against some HPV viruses associated with cervical cancer (Public Health Agency of Canada, 2010). The health care provider can be proactive by using the patient interview process to identify risk factors in adolescents. Once identified, the risk factors should lead to strategies for prevention.

The human immunodeficiency virus (HIV), which causes acquired immune deficiency syndrome (AIDS), is transmitted through unprotected sexual intercourse, the use of shared needles, and infected blood products (see Chapter 26). Therefore, the risk-taking behaviours of sexual activity and drug use make adolescents vulnerable to the threat of AIDS and other STIs. Adolescents who have placed themselves at risk for AIDS should be tested for HIV infection. All adolescents need improved knowledge about HIV and AIDS.

Pregnancy. Adolescent pregnancy occurs across socioeconomic classes, in public and private schools, among all ethnic and religious backgrounds, and in all parts of the country. Adolescent pregnancy with early prenatal supervision is considered less physically harmful to both mother and child than earlier believed. Pregnant teenagers need special education about nutrition, as well as health supervision and psychological support.

Health Concerns

Adolescents must form healthy habits of daily living. You need to emphasize the importance of exercise, sleep, nutrition, and stress reduction and to identify ways to adapt them to each adolescent. To do this, you must assess the individual's positive and negative habits and attitudes about health. Extensive and long-term follow-up is required if individualized interventions are to succeed. You must be aware of the prevalence of health problems and make assessments accordingly.

Health Education. Community and school-based health programs for adolescents focus on health promotion and illness prevention. You can become involved in community health through screening and teaching programs (Table 22-11).

Through primary health care efforts in the school and community, you can contribute to improvements in the health of adolescents. Discussions with adolescents must be private and confidential. Adolescents must first feel comfortable and respected as individuals to reveal intimate information about their risk-taking behaviours. Developing and implementing programs to respond to adolescents' needs are important strategies. Helping adolescents make decisions about their health care strengthens their autonomy and promotes healthy behaviours.

You can play an important role in preventing injuries and accidental deaths. Important activities include injury prevention activities; support of organizations that promote responsible behaviour, including Mothers Against Drunk Driving (MADD) and Drug Abuse Resistance Education (DARE); and encouragement of students to participate in organizations such as Students Against Drunk Driving (SADD). By stimulating adolescents to discuss alternatives to driving when under the influence of drugs or alcohol, you prepare them to consider alternatives when such an occasion arises. You need to identify adolescents at risk for substance abuse, provide education to

► TABLE 22-11

Health Promotion for Adolescents

Adolescent Health Concerns

Unintentional injuries

Firearm use and violence
Tobacco, alcohol, and
drug use

Suicide

Sexually transmitted
infections

Health Promotion Intervention

Advise adolescent to take a driver's education course and to wear seat belts.
Inform the adolescent of risk associated with drinking and driving and with use of drugs.
Promote helmet use by adolescents who use bicycles, motorcycles, all-terrain vehicles, and snow machines.
Ensure adolescent receives proper orientation in the use of all sports equipment.
Encourage adolescent to swim with a "buddy."
Teach conflict resolution skills.
Screen for tobacco (including smokeless), alcohol, and drug use, and inform adolescent of the risks of use.
Offer suicide prevention information.
Teach methods of dealing with a suicidal peer.
Promote suicide alternatives.
Provide adolescent with information regarding disease, mode of transmission, and related symptoms.
Encourage safer sexual practices, including abstinence from sexual activity or the use of condoms.
Provide accurate information about the consequences of sexual activity.

prevent accidents related to substance abuse, and provide counselling to patients in rehabilitation programs.

You can play a strategic role in an antismoking movement. Smoking prevention programs can be initiated in schools. Communities can also play a role in creating tobacco control policies at the local level (Sen & Wirjanto, 2010).

You need to provide sex education and counselling. You can play a key role in counselling teenagers on ways to avoid pregnancies. You can also assist adolescents in making decisions about pregnancies that do occur (e.g., becoming a parent, adoption, or abortion). Some schools have instituted day care programs so that adolescent mothers can continue their schooling after their babies are born. Whatever choice an adolescent makes, it is important that she receive appropriate health care, including counselling.

Extensive educational efforts to prevent the spread of AIDS and other STIs in this age group are a nursing responsibility. Formal or informal education, in a one-on-one or group setting, may be provided in the school or community. Speakers and organizations can be used to help in the educational process.

Adolescents in Rural Communities. Approximately 20% of Canadians live in rural areas and small towns; however, this percentage varies by province and territory. Although

adolescents living in these areas have many of the same health needs as their urban counterparts, they also have some unique risks. For example, those living on farms are at increased risks for accidents because of exposure to heavy equipment, huge vehicles, and large animals (Safe Kids Canada, 2010). Other concerns for adolescents living in rural areas and small towns are limited availability of recreational facilities and limited access to specialized services.

You can play an important role in improving the health of adolescents who live in rural areas. You can address decreasing barriers to care, health promotion education, development of coping strategies, and assessment of health beliefs.

Minority Adolescents. By the next century, it is expected that minorities as a group will become the majority. Minority adolescents have been identified as experiencing a greater percentage of health problems and barriers to health care.

Issues of concern for minority adolescents living in a high-risk environment include learning or emotional difficulties, death related to violence (e.g., “honour killing” of a female relative on the perceived grounds that she has dishonoured the family [Amnesty International, 2010]), unintentional injuries, and increased rates of adolescent pregnancy and STIs, including AIDS. Poverty has a major negative effect on the lives of minority adolescents. Access to culturally appropriate health services is commonly limited. You can make a significant contribution to improving access to appropriate health care for adolescents. Health promotion initiatives must be based on topics of concern for these adolescents.

It is important when working in the community that you adopt culturally sensitive interventions to meet the needs of minority adolescents and their families (Hockenberry & Wilson, 2011). You must be able to communicate in another language by speaking it or using an interpreter’s services. Educational materials need to be written in the appropriate language. Information regarding health beliefs and healing practices must be assessed. With knowledge about various cultures and the means to care for minority adolescents, you act as an advocate to ensure accessibility of appropriate services.

Aboriginal Adolescents. Health status and factors affecting it are generally worse for Canadian Aboriginal adolescents (i.e., First Nations, Inuit, and Métis) than any other adolescent populations (Leitch, 2007). Suicide rates are higher among Aboriginal youth than among other youth in Canada, especially among boys (MacNeil, 2008). Aboriginal adolescents are more likely to have crowded living conditions and to live in communities in which alcohol abuse and substance abuse are high. Likewise, the incidence of unemployment and reported sexual and physical abuse is higher than in non-Aboriginal communities (Health Canada, 2010a). Some problems persist for Aboriginal peoples, such as overcrowded living conditions and high rates of unemployment, when they live in urban areas of Canada.

When working with Aboriginal adolescents, you need to be aware of the unique factors that may affect these young people’s health. First, you need to be aware that health beliefs and practices, as well as health problems, vary among Aboriginal populations and communities. You need to be sensitive to culturally appropriate interventions. Many Aboriginal communities take responsibility for their own health and well-being, develop their own health services, and include traditional methods of healing to improve well-being.

Lesbian, Gay, and Bisexual Adolescents. Although research on lesbian, gay, and bisexual youth is limited, special

consideration must be given to the developmental and health challenges that may result from sexual orientation and societal attitudes to those orientations (Hockenberry & Wilson, 2011). It may be difficult for adolescents to discuss some of these challenges because of the stigma associated with being lesbian, gay, or bisexual. As a consequence, lesbian, gay, or bisexual adolescents could be at greater risk for emotional distress, depression, and suicide, as well as for alcohol or other drug abuse. Lesbian, gay, and bisexual youth need assistance with disclosing their sexual orientation and, before they disclose this information, a plan for dealing with negative and sometimes violent reactions. It is important to respond to these individuals in a sensitive and nonjudgemental way.

✦ KEY CONCEPTS

- A developmental perspective helps you understand commonalities and variations in each stage and the impact they have on the patient’s health.
- During the intrauterine period, while embryo and fetus grow and develop, genetic factors and environmental factors (teratogens) may cause impairments in any body system.
- Physiological, cognitive, and psychosocial development continue from conception through adolescence, and you must be familiar with normal parameters to determine potential problems and promote normal development.
- Physical growth during the school years is slow and steady until the skeletal growth spurt just before puberty.
- The major psychosocial developmental task of school-age children is the development of a sense of competence.
- Cognitively, young school-age children develop the ability to think in a logical manner.
- The prepubertal growth spurt usually occurs two years earlier in girls than in boys.
- Adolescents move forward to the last stage of cognitive development, formal operations, in which they begin to think in an abstract manner, reflect on thought processes, and plan for the future.
- Adolescence begins with puberty, when the primary sexual characteristic changes (maturation of the reproductive organs) and the secondary sexual characteristic changes (such as the development of pubic hair and female breasts) begin.
- Adolescents are able to solve complex mental problems by using deductive reasoning.
- Adolescents’ rapid change in physical appearance heightens self-consciousness and concerns regarding body image.
- Accidents are the major cause of death in all age groups.
- Motor vehicle accidents are the major cause of accidental death in adolescence.
- Adolescents begin the long process of emancipation from their parents and need parental support to accomplish this in a timely manner.

✦ CRITICAL THINKING EXERCISES

1. Ms. Yeigh, who is in her first trimester of pregnancy, is attending the antepartum clinic for the first visit. What are the main health promotion topics you need to explore with her at this stage in her pregnancy?
2. The parents of two-year-old Mark are concerned because his language does not seem to be at the same level as that of their neighbour’s two-year-old daughter. How would you reassure these parents and help them with language development?

3. Eight-year-old Lisa sometimes says to her parents that she feels "like a failure." According to Erickson's task for this stage of development, what measures can her parents and teacher use to help negate these feelings and help her meet this stage of development?
4. Twelve-year-old Maya is brought to the pediatric clinic for a physical examination. She is concerned about her lack of physical development in comparison with her peers. Discuss ways to educate Maya about puberty and the variations that occur.
5. Fifteen-year-old Ricardo wants very much to belong and be accepted by his peers. He expresses concern when his peers begin to plan a party with alcohol and drugs. What should be discussed to help support his feelings and need to belong?

❖ REVIEW QUESTIONS

1. Maternal risk factors associated with preterm labour include
 1. Physiological stresses, such as renal disease
 2. Ethnicity
 3. Fetal infections
 4. Nutrition
2. During a postpartum home visit, the public health nurse notes that Isabella is breastfeeding, and inquires about any breastfeeding issues. Isabella states that breastfeeding is going well. The father of the baby shares that he often encourages Isabella and reminds her about the benefits of breastfeeding. In response, the nurse should
 1. Explain to the father that he is putting undue pressure on the mother
 2. Encourage the father to continue supporting the mother
 3. Explain to the father that he has no role in breastfeeding
 4. Explain to the father that his well-intentioned behaviour is adversely affecting Isabella's breastfeeding
3. The recommended age for beginning immunization for diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP) in healthy children is
 1. 18 months
 2. 2 months
 3. 12 months
 4. 4 months
4. A toddler pretends to shave after watching his father shave. This is an example of Piaget's
 1. Sensorimotor stage
 2. Intuitive phase of preoperational thought stage
 3. Autonomy stage
 4. Preoperational thought stage
5. The type of play characteristic of the early preschool years is
 1. Selfish
 2. Onlooker
 3. Associative
 4. Parallel
6. Preschoolers sleep an average of
 1. 8 hours a night and take frequent naps
 2. 12 hours a night and take infrequent naps
 3. 10 hours a night and take frequent naps
 4. 6 hours a night and take frequent naps

7. The school nurse observes bite marks and round burns on eight-year-old Emma's arms. Upon questioning, the child tells the nurse, "Oh, that's nothing. I fell off my bike." Which of the following is the nurse's priority action?
 1. Speak to Emma's teacher about the observed injuries.
 2. Meet with the school principal about the observed injuries.
 3. Discuss the injuries with Emma's parents.
 4. Report the incident to the authorities.
8. The most common nutritional disturbance of childhood is
 1. Obesity
 2. Anorexia nervosa
 3. Type 2 diabetes
 4. Bulimia
9. When you are communicating with adolescents, it is best to
 1. Avoid discussing sensitive issues, such as asking questions about sex and drugs
 2. Ask closed-ended questions to get straight answers
 3. Be alert to clues to their emotional state
 4. Avoid looking for meaning behind adolescents' words or actions
10. The leading cause of death in adolescence is
 1. Homicide
 2. Substance abuse
 3. Injuries
 4. Eating disorders

❖ RECOMMENDED WEB SITES

Campaign 2000: <http://www.campaign2000.ca>

Campaign 2000 is a nonpartisan, cross-Canada coalition of more than 120 national, provincial, and community organizations committed to working together to end child and family poverty in Canada.

Canadian Coalition for Immunization Awareness and Promotion: <http://www.immunize.cpha.ca/en/default.aspx>

The Canadian Coalition for Immunization Awareness and Promotion (CCIAIP) is a partnership of national nongovernmental, professional, health, consumer, government, and private-sector organizations focused on promoting the understanding and use of vaccines recommended by the National Advisory Committee on Immunization. This Web site provides evidence-informed resources on immunization for parents and health care providers.

Canadian Institute of Child Health: <http://www.cich.ca/>

The Canadian Institute of Child Health (CICH) is a national charitable organization dedicated to promoting the health of children and youth in Canada. The CICH works with government and industry to address children's safety and health care issues and develop appropriate policies. This Web site offers evidence-informed resources of interest to health care provider, teachers, and parents.

Canadian Paediatric Society: Position Statements: <http://www.cps.ca/English/publications/StatementsIndex.htm>

This Web site includes the Canadian Paediatric Society's position statements on a variety of child health issues. It has updates as they are developed.

Young to Middle Adulthood

Original chapter by Patsy L. Ruchala, RN, DNSc

Canadian content written by J. Craig Phillips, RN, PhD, LLM, PMHCNS-BC, ACRN

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Discuss major life events and developmental tasks of young and middle-aged adults.
- Discuss the significance of family in the life of the adult.
- Describe normal physiological changes in young and middle adulthood, including pregnancy.
- Discuss cognitive and psychosocial changes that occur during the adult years.
- Describe health concerns of young and middle-aged adults.
- Apply clinical decision making to administer care to young and middle-aged adults.

key terms

Braxton-Hicks contractions, p. 366	Nesting, p. 366
Breastfeeding, p. 363	Peer navigator (doula), p. 364
Computer-mediated communication, p. 365	Perimenopause, p. 368
Erasure, p. 362	Prenatal care, p. 366
Infertility, p. 365	Puerperium, p. 366
Menopause, p. 368	Sandwich generation, p. 369

Young to middle adulthood is a period of challenges, rewards, and crises. Challenges may include the demands of working and raising families; rewards may include career, family, and personal successes; and crises may include job loss and caring for aging parents.

Adult developmental changes are unique to each individual. These changes are based on earlier characteristics and subsequent behaviours to adapt to these characteristics and new experiences. Young adulthood is the period between the late teens and the mid- to late 30s (Edelman & Mandle, 2010). Young adults constituted approximately 27% of the Canadian population in 2011 (Statistics Canada, 2012c). During young adulthood, individuals move away from their families of origin, establish career goals, and decide whether to marry and begin families or to remain single.

Middle age is the period between the mid- to late 30s and the mid-60s. During this period, people become aware of changes in reproductive and physical abilities

and may reassess life goals. In 2011, the median age of the Canadian population was 39.7 years of age and could rise to 44 years by 2040. This age group is growing because the baby-boomer generation is maturing and fertility rates in recent decades have declined (Statistics Canada, 2011).

Developmental theories provide you with a basis for understanding the life events and developmental tasks of young and middle-aged adults. Developmental theorists Erikson (1963, 1982), Havighurst (1972), and Gilligan (1993) described the phases of adulthood and related developmental tasks (see Chapter 21).

You may be a young or middle-aged adult yourself, coping with the demands of your respective developmental period. You must be careful to recognize and respect the needs of your patients even if you are not experiencing the same challenges and events. You can help young and middle-aged adult patients achieve their potential by offering support and providing information and appropriate referrals.

Young Adulthood

Physical Changes

Most young adults have completed physical growth by the age of 20 years. Young adults are usually quite active, experience fewer severe illnesses than do older age groups, tend to ignore physical symptoms of illness, and often postpone seeking health care. Physical characteristics of young adults begin to change as middle age approaches.

Patients in this developmental stage may benefit from a personal lifestyle assessment to identify habits that increase the risk for cardiac, malignant, pulmonary, renal, or other chronic diseases. A personal lifestyle assessment of the young adult includes assessment of general life satisfaction; hobbies and interests; habits (e.g., diet, sleep, exercise, sexual practices, caffeine use, alcohol, illicit drugs); home conditions (e.g., housing, finances); and occupational environment (e.g., type of work, exposure to hazardous substances, physical or mental strain).

Cognitive Changes

Cognitive changes are variations in reasoning and thinking. Critical thinking habits increase steadily through the young and middle adult years. Formal and informal education, life experiences, and work opportunities increase the individual's conceptual and problem-solving skills. Young adults with flexible decision-making processes cope most effectively by continually evolving and adjusting to changes in their home, workplace, and personal lives.

Choosing an occupation is a major task of young adults and involves knowing their skills, talents, and personality characteristics. The lack of resources or support systems to pursue higher education or develop work skills may limit occupational choices for many young adults.

By understanding how adults learn, you can develop teaching plans (see Chapter 20). Adults enter learning situations with a background of unique life experiences, including illness. Therefore, you should always view each adult as an individual. When determining what amount of information the individual needs to make decisions about the prescribed course of therapy, you should consider factors that may affect the individual's adherence to the regimen, including educational level, socioeconomic factors, social context factors (Phillips, 2011), motivation, and desire to learn.

Psychosocial Changes

The emotional health of young adults is related to their ability to address and resolve personal and social tasks. Young adults often want to prolong adolescence and yet assume adult commitments. Between the ages of 23 and 28 years, people usually refine self-perception and capacity for intimacy. From ages 29 to 34 years, people usually focus on achieving personal and occupational goals and improving socioeconomic status. For many young adults, a dual-income family is needed to achieve and maintain middle-class status. Career and personal counselling can help individuals identify career choices and set realistic goals.

Ethnicity and gender issues influence an adult's life and can pose challenges for nursing care. Each person holds culture-bound definitions of health and illness. An understanding of ethnicity, race, and gender differences enables you to provide individualized care (see Chapter 9). Traditional gender roles of men and women have changed and have resulted in alterations in traditional familial structures. Since the 1970s, women have been entering the workforce and pursuing careers in high numbers. About 62% of Canadian women aged 15 years and older are in the labour force (Statistics Canada, 2012e). Women contribute significantly to their families' incomes. As a result, many women deal with the stresses of being wife, mother, and employee. Likewise, men are assuming more parental and household responsibilities (Austin & Boyd, 2010). Some men choose to put careers on hold to be stay-at-home fathers. Challenges may arise for young adults who do not conform to traditional gender roles. Gay, lesbian, bisexual, intersex, transgender, Two Spirit, queer, and questioning persons may face challenges in navigating the health care system and social context to lead happy and healthy lives (Phillips & Saewyc, 2010). For transgender persons, this may be particularly challenging due to "erasure"—the social process through which transsexuality is managed in cultures and institutions as being ultimately impossible (Bauer et al., 2009; Namaste, 2000). **Erasure** describes how sexual minority identities are systematically "erased" from heteronormative society by allowing only gender binary (male/female) on health records and other documents; in a society, transgender persons are systematically erased (Bauer et al., 2009; Namaste, 2000). For other sexual minorities, the common use of the epidemiological categories of men who have sex with men (MSM) and women who have sex with women (WSW) serves to "erase" the existence of gay and lesbian communities (Boellstorff, 2011; Prestage, 2011; Young & Meyer, 2005). "Two Spirit is a term used to describe Aboriginal people who assume cross-, or multiple gender roles, attributes, dress and attitudes for personal, spiritual, cultural, ceremonial, or social reasons. These roles are defined by each [Aboriginal] cultural group and can be fluid over a person's lifetime. Modern terms like gay, lesbian, bisexual, transgender (GLBT), transsexual and intersexed (in combination with, or exclusive to, Two Spirit) may be adopted by some Aboriginal people to define who they are" (Manitoba Health, 2004, p. 47).

Career. Young men and women hope to have fulfilling careers. They may formulate short- and long-term career goals. Successful employment ensures economic security and promotes friendships, social activities, support, and self-respect.

In many two-career partnerships, the benefits experienced (e.g., improved finances) may outweigh potential stressors (e.g., child care demands; household needs; increased physical, mental, or emotional demands). To reduce stress in a two-career family, neither partner should assume all household

responsibilities. For some families, a solution is to hire a housekeeper. Others may set up an equal division of household and child care duties.

Sexuality. Young adults usually have the emotional maturity necessary to establish intimacy and develop fulfilling sexual relationships. Young adults who have failed to achieve the developmental tasks of adolescence may develop superficial relationships (Austin & Boyd, 2010).

For most young adults, the emotional aspect of sexual activity is as important as its type or frequency. Understanding the differences between sexual desire (i.e., responses to physical and mental stimuli during or in anticipation of sexual activity), sexual behaviour (i.e., how humans experience and express their sexuality), and sexual identity (i.e., how a person identifies their sexuality) will facilitate your work with young adult patients (Wolitski et al., 2007). Recognizing the distinct differences between each and how they are influenced by internal and external factors will facilitate open dialogue and collaborative approaches to patient teaching about sexual health. This open dialogue will reduce potential sexual health risks, including HIV and other sexually transmitted infections (Phillips & Saewyc, 2010). Adults should be encouraged to explore various aspects of their sexuality and be aware that their sexual needs and concerns evolve (see Chapter 26).

Singlehood. Social pressure to get married is not as great as it once was. During the 2006 to 2011 census period, families and living arrangements among Canadians continued to diversify. Married families accounted for two-thirds of all families. Common-law couples and lone-parent families increased, and for the first time, common-law couples outnumbered lone-parent families. The 2011 census cycle is the first full cycle in which all areas of Canada recognized same-sex marriage, and the number of same-sex marriages increased by 42% between 2006 and 2011 (Statistics Canada, 2012b). Young adults who choose to remain single and maintain independence may consider siblings and parents as their family. However, close friends and associates may also be viewed as the individual's "family." Some singles choose to become parents, either biologically or through adoption.

The single population is increasing partly because women have greater career opportunities than before and partly because single individuals often choose to live together and share housing costs rather than marry. In addition, many adults become single again after a marriage ends.

Marriage. Every married couple's relationship is unique, regardless of the gender makeup of the couple. Although no rules guarantee a successful marriage, some guidelines are useful for building a happy marriage. Before marriage, the couple ideally should (1) ensure that their emotions are based on love rather than physical attraction, (2) explore their motivations for marriage, (3) develop clear communication, (4) accept that behaviour and habits are unlikely to change after marriage, and (5) determine their compatibility in important beliefs and values.

When establishing a household and family, the married couple must work as a team. Individuals require maturity and self-esteem to accomplish the following major tasks of marriage: establishing an intimate relationship; deciding on and working toward mutual goals; establishing guidelines for decision-making issues; setting standards for social interactions; and choosing morals, values, and ideologies acceptable to both. Accomplishing these tasks provides the foundation for a stable relationship.

* BOX 23-1

FOCUS ON PRIMARY HEALTH CARE

Preparation for Parenthood

Preparing for child-bearing and parenthood involves many decisions and choices for the child-bearing family. These include the decision to have a baby and the choices of health care provider, place of birth, how to obtain information and prepare for child-birth, and how to feed and care for the newborn.

In a hospital or community prenatal clinic, you have many opportunities to assist the child-bearing family by providing information that aids decision making. You may help families to seek preconceptional counselling for known or suspected health risks that might affect the mother or fetus during pregnancy. You may also refer families to other health care providers for unique concerns. By providing a list of questions that could be asked of a health care provider on a first visit, you may encourage expectant parents to select a health care provider with whom they will be comfortable and who will meet their needs.

Prenatal education programs offered by hospital and community nurses and by midwives provide information about coping strategies and support during pregnancy, labour, and the early postpartum period. Classes specifically about preparation for Caesarean birth or for siblings and grandparents may also be available. Prenatal education programs should be structured to meet the unique needs, goals, and learning styles of the expectant family.

Adapted from Olds, S. B., London, M. L., Ladewig, P. A., & Davidson, M. R. (Eds.). (2004). *Maternal-newborn nursing and women's health care* (7th ed., pp. 285–293). Upper Saddle River, NJ: Pearson Prentice Hall.

Marriage also requires the couple to learn patterns of sexual expression, establish roles, and practise effective conflict resolution and decision-making skills. Each partner may experience a sense of loss of individuality in the transition from being single to being married.

Child-Bearing Cycle. Conception, pregnancy, birth, and the puerperium (postpartum period) are phases of the child-bearing cycle. The changes during these phases are complex (Box 23-1). Childbirth education classes can prepare the pregnant woman, her partner, and other supportive people to participate in the birthing process. Pregnant women and their families may benefit from a lay doula (support person).

Breastfeeding offers many advantages to both the new mother and baby (see Chapter 42). However, for the inexperienced mother, breastfeeding may cause anxiety and frustration. Women who have had no contact with newborns and other mothers who breastfeed may require assistance to breastfeed successfully. You must be alert for signs that the mother needs information and assistance. By observing the mother while she breastfeeds, you may catch problems such as improper positioning or ineffective sucking by the infant (Registered Nurses' Association of Ontario, 2003).

The personal and social changes occurring in the lives of a couple after the birth of a baby cannot be underestimated. Nursing assessment of the couple's response to the birthing experience and parent-child attachment are discussed later in this chapter.

Parenthood. Contraception allows couples to decide when and whether to start a family. One factor influencing this decision is the reason for wanting a child. Social pressures may encourage a couple to have a child or may influence them to

► BOX 23-2 Ten Hallmarks of Emotional Health

- A sense of meaning and direction in life
- Successful negotiation through transitions
- Absence of feelings of being cheated or disappointed by life
- Attainment of several long-term goals
- Satisfaction with personal growth and development
- When married, feelings of love for partner; when single, satisfaction with social interactions
- Satisfaction with friendships
- Generally cheerful attitude
- Acceptance of constructive criticism
- No unrealistic fears

limit the number of children they have. Economic considerations frequently enter into the decision because raising children is expensive. Because couples are getting married later and are postponing pregnancies, general health status and age are also factors in whether a couple decides to have children.

Parenting roles must be defined and practised. Nurturing and socialization needs of children can put pressure on the couple's intimate relationship. In addition, parents' images of the "perfect parent" may conflict with reality.

Alternative Family Structures and Parenting.

Norms and values about family life in Canada continuously evolve, as demonstrated by judicial rulings on same-sex marriage since 2000. Greater numbers of infants are born to cohabiting (common-law) couples (see Chapter 19). Families may include single parents, same-sex couples, or be combined from previous relationships. Parents from alternative family structures may perceive lack of support and bias from the health care system (McManus et al., 2006). Same-sex parents and their children may need support for adoption of children and the parenting role.

Hallmarks of Emotional Health

Most young adults have the physical and emotional resources and support systems to meet their many challenges, tasks, and responsibilities. During psychosocial assessment of young adults, you can assess for 10 hallmarks of emotional health that indicate successful maturation in this developmental stage (Box 23-2). If one or more of these hallmarks are not attained, further assessment and action may be required.

Social Support in Health and Illness

A current trend in health care is the use of **peer navigators** to facilitate well-being (Figure 23-1). This trend is evident in states of health when a family uses the services of a **doula** to help a pregnant woman and her family to navigate the challenges of pregnancy. In chronic disease states such as cancer, mental illness, and HIV disease, peer navigators can help patients to navigate the complexities of the health care system and therapeutic regimens (Box 23-3).

Health Risks

Health risk factors for a young adult originate in lifestyle patterns, family history, and the environment and occupation.

Lifestyle. Lifestyle habits such as poor food choices, smoking, stress, high-risk sexual behaviour, substance abuse, and inactivity increase the risk of illness. For example, prolonged stress can cause ulcers, emotional disorders, and infections (see Chapter 29). Smoking and second-hand smoke

Figure 23-1 A peer navigator and patient discuss medication adherence strategies.

* BOX 23-3 RESEARCH HIGHLIGHT

Peer Navigators: Social Support During Health Challenges

Research Focus

The importance of social supports for managing health and illness are gaining momentum. For example, Wittenberg et al. (2010) studied the relationships between marital status, distress, and well-being among women newly diagnosed with breast cancer and their peer navigators.

Research Abstract

The purpose of Wittenberg et al.'s study was to describe the effect of marital status on changes in distress and well-being among women who were newly diagnosed with breast cancer and their cancer survivor peer navigators. The peer navigator provided one-on-one peer counselling for three to six months. Findings indicated that married or partnered women newly diagnosed with breast cancer experienced the added benefit of social support from their partner and their peer navigator. The women experienced reductions in depressive symptoms and improvements in emotional well-being. Peer navigators were observed to have better well-being with continued training and additional support. This study reinforces the importance of social supports for managing illness such as breast cancer.

Evidence-Informed Practice

- Provision of ongoing training and support to peer navigators is important for their continued well-being.
- Single or not-married peer navigators may re-experience trauma if they do not have adequate social support.
- Women diagnosed with breast cancer that are not married or partnered require additional support and a peer navigator may help reduce depressive symptoms.

Reference: Wittneberg, L., Yutsis, M., Taylor, S., Giese-Davis, J., Bliss-Isberg, C., Star, P., & Spiegel, D. (2010). Marital status predicts change in distress and well-being in women newly diagnosed with breast cancer and their peer counselors. *Breast Journal*, 16(5), 481–489.

can cause lung cancer and pulmonary, cardiac, and vascular diseases. **Computer-mediated communication** (e.g., Internet dating, “sexting”) can lead to high-risk sexual encounters and adverse health outcomes (Phillips & Saewyc, 2010). Your role in health promotion is to identify lifestyle risk factors and provide education and support to reduce unhealthy behaviours.

Family History. A family history of a disease may put a young adult at risk for developing that disease in the middle or older adult years. For example, a family history of certain cancers or cardiovascular, renal, endocrine, or neoplastic disease increases the family member’s risk of developing the disease.

Accidental Death and Injury. Accidents are the leading causes of injury and death in young adults (Lewis et al., 2010). Death and injury can result from motor vehicle or other accidents, physical assaults, and suicide attempts. Among 19- to 24-year-olds, the leading causes of death in 2009 were accidents and intentional self-harm (suicide) (Statistics Canada, 2012f). They also may cause permanent disability.

Physical assault and violence may also cause injury or death. Factors that may predispose to violence include poverty, breakdown of family relations, child abuse and neglect, and access to firearms. To detect personal and environmental risk factors for violence, it is important that you perform a thorough psychosocial assessment, including such factors as behaviour patterns, history of physical abuse and substance abuse, education, work history, and social support systems.

Substance Abuse. Substance abuse directly or indirectly contributes to mortality and morbidity in young adults. Regular heavy drinking (five or more drinks on one occasion) is most common among Canadians aged 20 to 34, and twice as many men in this age group drink compared to women in the same age range (Statistics Canada, 2012d). Intoxication is often a factor in motor vehicle accidents.

Dependence on stimulants (“uppers”) can result in overdose death by putting stress on the cardiovascular and nervous systems. Use of depressants (“downers”) can lead to accidental or intentional overdose and death. You can provide counselling and support for patients seeking treatment for substance abuse.

Substance abuse cannot always be diagnosed, particularly in its early stages. Nonjudgemental questions about use of legal drugs (prescribed drugs, over-the-counter drugs, tobacco, and alcohol), so-called soft drugs (marijuana), and illegal drugs (cocaine or heroin) should be a routine part of any physical assessment. Important information may be obtained by making specific inquiries about past medical problems, changes in food intake or sleep patterns, or problems of emotional lability. Reports of arrests because of driving while intoxicated, because of domestic or child abuse, or because of disorderly conduct should alert you to the possibility of drug misuse or abuse.

Unplanned Pregnancies. Unplanned pregnancies, although more common among adolescents, also occur in young and middle-adult Canadian women. Unplanned pregnancies are a source of stress that can result in adverse health outcomes for the mother, infant, and family. Many young adults have educational and career goals that take precedence over family development. Interference with these goals can affect future relationships and later parent-child relationships. When assessing the woman with an unplanned pregnancy, determination of the situational factors that affect pregnancy outcome is important. These include exploring issues such as

family support systems; potential parenting disorders; depression; coping mechanisms; and possible financial, career, or housing problems.

Sexually Transmitted Infections. Sexually transmitted infections (STI) are a major health problem in young adults (Public Health Agency of Canada, 2010; Society of Obstetricians and Gynaecologists of Canada, 2006). STIs include syphilis, chlamydia, gonorrhea, genital herpes, human papilloma virus (HPV) infection, and human immunodeficiency virus (HIV) disease (see Chapter 26). STIs have immediate physical effects such as discharge and discomfort. STIs also can lead to chronic disorders (from genital herpes), infertility (from gonorrhea), or death. Many people have an STI without experiencing symptoms. Young adults need information about transmission, prevention, symptoms, and management of STIs.

Many young adults have misconceptions regarding transmission and treatment of STIs. Partners are encouraged to know one another’s sexual history and sexual practices. You should be alert for STIs when patients come to clinics with complaints of urological or gynecological problems (see Chapter 31). Young adults should be assessed for their knowledge and use of safer sex practices and genital self-examinations.

Environmental or Occupational Factors. A common environmental or occupational risk factor is exposure to work-related hazards or agents. Diseases observed in workplaces include silicosis from inhalation of talcum and silicon dust, emphysema from inhalation of smoke, and hearing loss from noise exposure. Cancers resulting from occupational exposures may involve the lungs, liver, brain, blood, or skin. Environmental exposures with leisure activities include outdoor exposure to mosquitoes (which may transmit West Nile virus) and ticks (which may transmit Lyme disease). Questions regarding environmental and occupational exposures should be a routine part of your assessment.

Health Concerns

Infertility. Infertility refers to a lack of conception after a reasonable period of sexual intercourse without contraception (Assisted Human Reproduction Canada, 2010). Infertility affects as many as one in eight couples. For many couples, the use of infertility clinics can facilitate pregnancy. The cause of infertility is unknown in about 20% of affected couples. Female factors, such as ovulatory dysfunction or a pelvic factor, and male factors, such as sperm and semen abnormalities, are responsible for about 80% of cases of infertility (Breslin & Lucas, 2003). Couples who delay conception until their mid-30s may experience fertility problems. For some infertile couples, you may be the first resource contacted. Nursing assessment of infertile couples should include comprehensive histories of both partners to determine factors that may affect fertility, as well as pertinent physical findings (Lowdermilk et al., 2011).

Exercise. Exercise patterns can affect health status. Exercise three times a week that produces a sustained increase in the pulse rate for 15 to 20 minutes improves cardiopulmonary function by decreasing blood pressure and heart rate. In addition, exercise decreases fatigue, insomnia, tension, and irritability. You should conduct a thorough musculoskeletal assessment, including evaluations of joint mobility and muscle tone, and a psychosocial assessment for improved tolerance of stress to determine the effects of exercise.

Routine Health Screening. Routine screening examinations lower the risk for severe illnesses and enable early detection. Patients should be encouraged to perform monthly

skin, breast, or male genital self-examination (see Chapter 31). In Canada, cancer is the leading cause of death; lung and colorectal cancer are the most prevalent. The highest incidence of cancer is among persons over the age of 50, but cancer contributes to illness and death in young and middle-aged adults (Canadian Cancer Society's Steering Committee, 2010). Breast and male genital cancers continue to be considerable issues in Canada. Therefore, your role is extremely important in educating patients about breast self-examination and the current breast screening recommendations, and you must provide male patients with information about testicular self-examination and prostate cancer screening. In adolescence and early adulthood, prolonged exposure to ultraviolet rays from the sun or in tanning salons can increase the risk for development of skin cancer. Encourage patients to undergo routine assessment of the skin for changes in colour or presence of lesions and changes in their appearance. Persons living with chronic conditions such as cancer, diabetes mellitus, or HIV may require specific condition-related screenings on a routine basis (Figure 23-2).

Job Stress. Job stress can occur every day or periodically. Most young adults are able to handle day-to-day crises. Situational job stress may occur when a new boss enters the workplace, a deadline is approaching, or the worker is given new responsibilities. Corporate restructuring may lead to layoffs and increased responsibilities for remaining employees and is a major source of stress. Job stress also occurs when a person becomes dissatisfied with a job. Because individuals perceive jobs differently, the types of job stressors vary from person to person. Your assessment of the young adult should include a description of the adult's work, including conditions and hours, duration of employment, changes in sleep or eating habits, and evidence of increased irritability or nervousness.

Family Stress. Family stressors can occur at any time in family life. Family life is a dynamic process that includes times when everyone in the family works together and times when everyone appears to pull apart. Situational stressors occur during events such as births, deaths, illnesses, marriages, and job losses. Because of changing relationships and structures in the emerging young adult family, stress levels are frequently high and may be related to a number of variables that may

lead to family dysfunction. Stress and the possible resulting family dysfunction may account for high divorce rates during the first three to five years of marriage for young adult couples. When a patient seeks health care and exhibits stress-related symptoms, you should ask whether the person has recently experienced a life-changing event.

Each family has certain predictable roles or jobs for members. These roles enable the family to function and be an effective part of society. One necessary role is the family leader. In most families, one parent is the leader or both parents act as co-leaders. In lone-parent families, the parent or, on occasion, a member of the extended family is the family leader. When this role changes as a result of illness, a situational crisis may occur. You should assess environmental and familial factors, including support systems and coping mechanisms commonly used by family members.

Pregnancy. Although the physiological changes of pregnancy and childbirth occur only in women, cognitive and psychosocial changes and health concerns affect the entire child-bearing family (Somers-Smith, 1999). The entire family, therefore, needs education about pregnancy, labour, delivery, breastfeeding, and integration of the newborn into the family structure.

Women and men who are anticipating pregnancy benefit from good health practices before conception, including eating a balanced diet, exercising, attending regular dental checkups, and avoiding alcohol, drugs, and smoking. Women trying to become pregnant should not follow weight-reduction diets.

Prenatal Care. Prenatal care includes routine assessment of the pregnant woman by a nurse, family physician, obstetrician, nurse practitioner, or midwife. Health promotion interventions are important during the prenatal period and can improve the well-being of the woman and fetus (Box 23-4). Prenatal care includes a thorough physical assessment of the pregnant woman during regularly scheduled intervals; provision of information regarding STIs, vaginal infections, and urinary infections that could adversely affect the fetus; and counselling about exercise patterns, diet, and child care. Regular prenatal care can address health concerns that arise during the pregnancy.

Physiological Changes. The physiological changes and needs of the pregnant woman vary with each trimester (Table 23-1). Temporary changes in visual and hearing acuity, taste, and smell also occur. You must be familiar with these physiological changes, their causes, and helpful interventions. All women experience some physiological changes in the first trimester, but some changes affect only certain women. During the second trimester, growth of the uterus and fetus results in some of the physical signs of pregnancy, and the woman will see her growing abdomen and feel fetal movements. During the third trimester, irregular, short contractions (**Braxton-Hicks contractions**), fatigue, and urinary frequency may occur. Close to the onset of labour, the woman may experience a burst of energy during which she prepares for the baby's arrival, a period called **nesting**.

The **puerperium** is a period of approximately six weeks after delivery. During this time, the woman's body reverts to its prepregnant physical status. You should assess the woman's knowledge of and ability to care for both herself and her newborn. Assistance with infant feeding and care and assessment of parenting skills and mother-infant interactions are particularly important (Dunn et al., 2006). During this period, you should assess for postpartum depression, which may

Figure 23-2 Routine health screening for persons living with chronic conditions.

BOX 23-4 NURSING STORY

Support During Pregnancy

Melinda was a 24-year-old woman pregnant with her first child. Her pregnancy was healthy and the fetus appeared to be growing well. Beginning in her sixth month of pregnancy, she enrolled in childbirth education classes, taught by a community health nurse. The nurse noticed that Melinda's boyfriend, Troy, accompanied her to the first class. During the second class, the nurse observed that Melinda was by herself and appeared a bit withdrawn. Concerned about whether Melinda would have adequate support during labour and birth, the nurse asked Melinda whether Troy was going to be coming back. Melinda replied that Troy had gone up north to work and would be gone for at least three months. She said she missed him already and was worried that he might miss the birth, because the camp where he worked was very remote. Because only a few flights a week were available, Melinda was not sure he would be able to leave when she went into labour. The nurse asked Melinda about other family members who might be able to support her. Melinda said she is estranged from her mother, but her 19-year-old sister might be able to be with her for the birth, if she can take time off work. The nurse suggested that Melinda consider arranging to have a doula present during labour to offer physical, emotional, and informational support. The doula would meet with Melinda sometime before her due date to talk with her about what would be most helpful to her during labour and would be at her side through the birth. The nurse provided several names of doulas and encouraged Melinda to consider this as an additional support person in case her boyfriend or sister could not make it in time. During the next class, Melinda said that she had contacted a doula and made arrangements to meet with her. She stated that she was relieved to know that she would have labour support if Troy could not attend the birth. She was very appreciative of the nurse's help. Several months later, Melinda phoned the nurse to say that Troy caught a flight in time and that both he and the doula had really helped her during the birth and they were thrilled to have given birth to a healthy baby boy.

include maladaptive coping strategies and ineffective bonding interactions between mother and newborn.

Psychosocial Changes. Like the physiological changes of pregnancy, psychosocial changes may occur at various times during pregnancy and in the puerperium. Table 23-2 summarizes the major categories of psychosocial changes and implications for nursing intervention.

Acute Care. The young adult years are generally a time of good physical and emotional health. Potential health hazards may be related to lifestyle. Acute care for young adults is frequently related to accidents, substance abuse, exposure to environmental and occupational hazards, stress-related illnesses, respiratory infections, gastroenteritis, influenza, urinary tract infections, and minor surgery.

An acute, minor illness can cause a disruption in the life activities of the young adult and increase stress in an already hectic lifestyle. Dependency and limitations posed by treatment regimens can also increase frustration for the young adult. To give young adults control of their health care choices, it is important for you to keep them informed about their health status and involve them in health care decisions. Acute phases of chronic illnesses may pose challenges for young adults.

Restorative and Continuing Care. Chronic conditions in young adulthood, although not common, do occur.

► TABLE 23-1

Major Physiological Changes During Pregnancy

Signs and Symptoms

Causes

First Trimester

Amenorrhea	Fertilization and implantation of egg
"Morning sickness" (nausea, sometimes vomiting)	Increases in hormone levels
Breast changes: enlargement, tenderness, darkened and enlarged nipples	Increased serum hormone levels
Urinary frequency	Increased estrogen levels
Fatigue	Pressure of uterus on bladder
	Increased nutritional demands
	Decreased nutritional intake resulting from morning sickness

Second Trimester

Integumentary changes: pigment changes in nipple and breast, hyperpigmentation of abdominal line (linea nigra), mottling of cheeks or forehead (chloasma, or "mask of pregnancy"), localized or generalized pruritis	Increased levels of melanocyte-stimulating hormone
Hypertrophy of gums, causing gingival swelling and bleeding	Proliferation of interdental papillary blood vessels, caused by increased estrogen levels
Increasing height of uterine fundus	Growth of fetus
Sensation of movement or of abdominal gas (quickening)	Fetal movement

Third Trimester

Braxton-Hicks contractions	Expansion and preparation of uterus for labour
Increased colostrum	Hormonal influence; preparation of breasts for lactation
Increased urinary frequency	Pressure on bladder from enlarged fetus
Shortness of breath	Pressure on diaphragm from enlarged uterus
Supine hypertension	Uterine pressure on inferior vena cava
Heartburn	Slower gastric emptying and esophageal reflux

Data from Lowdermilk, D., Perry, S., & Cashion, M. C. (2011). *Maternity nursing* (8th ed.). St Louis, MO: Mosby.

Chronic illnesses such as hypertension, coronary artery disease, and diabetes may have their onset in young adulthood without being known to the young adult until later in life. Causes of chronic illness and disability in a young adult can include accidents, multiple sclerosis, rheumatoid arthritis, HIV, and cancer. Chronic illness and disability can affect the accomplishment of important developmental tasks in young adulthood.

► TABLE 23-2

Major Psychosocial Changes During Pregnancy

Type of Change	Implications for Nursing Intervention
Body image	Morning sickness and fatigue may contribute to poor body image. Increase in breast size may make the woman feel more feminine and sexually appealing but may also be uncomfortable. The woman begins to “show” during the second trimester. The woman may experience a general feeling of well-being; she can feel the baby move and hear the baby’s heartbeat.
Role changes	Both partners think about impending role changes and can have feelings of uncertainty about them. Both partners may have feelings of ambivalence about becoming parents and concern about ability to be parents.
Sexuality	Partners need reassurance that sexual activity will not harm the fetus. Desire for sexual activity may be influenced by body image. Partners may desire cuddling and holding rather than sexual intercourse.
Coping mechanisms	Partners need reassurance that childbirth and child-rearing are natural and positive experiences but can also be stressful. Partners should be provided guidance in preparation for childbirth and encouraged to participate in childbirth classes.
Stresses during puerperium	Partners may return home from hospital fatigued and unfamiliar with infant care. Partners may experience physical discomfort or feelings of anxiety. The woman may have to return to work soon after delivery, with subsequent feelings of guilt, anxiety, or, possibly, sense of freedom or relief.
Postpartum blues and depression	Postpartum blues symptoms include transient emotional or mood disturbances such as weepiness, insomnia, anxiety, and poor concentration about 3 to 6 days after birth. Postpartum depression symptoms include extreme anxiety, sense of failure, feelings of guilt, sleep disturbances, appetite disorders, excessive concerns about the baby, and suicide ideation. Interventions include medication, therapy, counselling, and support.

They can reduce a young adult’s independence and require the person to change personal, family, and career goals. A young adult with chronic illness or disability may experience developmental problems related to sense of identity. The person needs support in the establishment of independence, reorganization of intimate relationships and family structure, and launching of a chosen career (Lewis et al., 2010).

Middle Adulthood

The middle adult years begin around the early to mid-30s and last through the mid-60s. Personal and career achievements have often already been experienced. Many middle-aged adults enjoy assisting their children and other young people to become productive and responsible adults. Middle-aged adults may also begin to help aging parents. Technology has an increasing impact on work, pleasure, and play for middle-aged adults. Using leisure time in satisfying and creative ways is a challenge that, if met satisfactorily, enables middle-aged adults to prepare for retirement. Socioeconomic instability brought on by corporate restructuring and economic realities may leave many middle-aged adults either jobless or forced to accept lower-paying jobs.

Men and women must adjust to inevitable biological changes. Middle-aged adults adapt self-concept and body image to physiological realities and changes in physical appearance. Exercising, eating well, getting enough sleep, and practising good hygiene promote good health and a positive attitude toward physiological changes.

Physical Changes

Major physiological changes occur between the ages of 40 and 65 years. Table 23-3 summarizes normal developmental changes that you consider when conducting a physical examination. The most visible changes are greying of the hair, wrinkling of the skin, and thickening of the waist. Decreases in hearing and visual acuity are often noted during this period. These physiological changes may affect the person’s self-concept and body image. For women, the most significant physiological change during middle age is menopause. Men may also notice several sexual changes as androgen levels decrease, such as less firm erections and less frequent ejaculation (see Chapter 26). However, many middle-aged men are still capable of producing fertile sperm and fathering a child.

Perimenopause and Menopause. Menstruation and ovulation occur in a cyclical rhythm in women from adolescence into middle adulthood. **Perimenopause** is the period during which ovarian function declines, which results in a diminishing number of ova and irregular menstrual cycles. During this perimenopause time, however, women can still become pregnant. **Menopause** is the permanent cessation of menstruation. It occurs primarily because the ovaries stop producing the hormones estrogen and progesterone. Menopause typically occurs between the ages of 45 and 60 years. The presence and experience of menopausal symptoms, such as hot flashes and insomnia, varies among women from being asymptomatic to being severe enough to interfere with activities of daily living (Condon, 2004).

Cognitive Changes

Changes in the cognitive function of middle-aged adults are rare except with illness or trauma. The middle-aged adult can learn new skills and information. Some middle-aged adults enter educational or vocational programs to prepare themselves for entering the job market or changing jobs.

Psychosocial Changes

The psychosocial changes in middle-aged adults may involve expected events, such as children moving away from home, or unexpected events, such as a marital separation or the death of a loved one. Many middle-aged adults may find themselves

► TABLE 23-3

**Physical Assessment Findings
in the Middle-Aged Adult**

Body System	Expected Findings
Integument	Intact condition Appropriate distribution of pigmentation Slow, progressive decrease in skin turgor Greying and loss of hair (baldness patterns in men are established by age 55; hair loss after this time might have other causes)
Head and neck	Symmetry of scalp, skull, and face
Eyes	Normal accessory organs of vision Visual acuity (according to Snellen chart) that is less than 20/50 Normal pupillary reaction to light and accommodation Normal visual fields and extraocular movements Normal retinal structures
Ears	Normal auditory structures and acuity
Nose, sinuses, and throat	Patent nares and intact sinuses, mouth, and pharynx Location of trachea at midline Nonpalpable lateral thyroid lobes
Thorax and lungs	Increased anteroposterior diameter Respiratory rate: 12–20 breaths per minute and regular Ratio of respiratory rate to heart rate: 1:4 Normal tactile fremitus, resonance, and breath sounds
Heart and vascular system	Normal heart sounds Systole: first heart sound loudest at apex Diastole: first heart sound loudest at base Point of maximal impulse: at fifth intercostal space in midclavicular line and 2 cm or less in diameter Temperature: 36.1°C–37.6°C Pulse: 60–100 bpm (in conditioned athlete, 50 bpm) Blood pressure: 130 mm Hg systolic, 85 mm Hg diastolic All pulses palpable
Breasts	Decreased size resulting from decreased muscle mass Normal nipples
Abdomen	No tenderness or organomegaly Decreased strength of abdominal muscles
Female reproductive system	Change in menstrual cycle and in duration and quality of menstrual flow to cessation of menses “Hot flashes”
Male reproductive system	Normal penis and scrotum Prostatic enlargement in some individuals
Musculoskeletal system	Decreased muscle mass Decreased range of joint motion
Neurological system	Appropriate affect, appearance, and behaviour Lucidity and appropriate level of cognitive ability Intact cranial nerves Adequate motor responses Responsive sensory system

in the so-called **sandwich generation**, simultaneously having the responsibilities of raising their own children and caring for aging parents. These changes may result in stress that can affect middle-aged adults' overall health. During middle age, the person examines life goals and relationships. Often a “midlife crisis” results, in which the person feels turmoil or anxiety about the course of his or her life and desires change. As a result, the person may change relationships, lifestyle, or occupation.

You should assess the major life changes occurring in the middle-aged adult and the impact that the changes have on that person's state of health. Your assessment should also include individual psychosocial factors such as coping mechanisms and sources of social support.

In the middle adult years, as children depart from the household, the family enters the postparental family stage. Time and financial demands on the parents decrease, and the couple faces the task of redefining their relationship. If grandchildren are born, grandparenting styles must be chosen. Many middle-aged adults begin to adopt a healthier lifestyle. Health promotion needs for the middle-aged adult include adequate rest, leisure activities, regular exercise, good nutrition, reduction or cessation in the use of tobacco or alcohol, and regular screening examinations. A middle-aged adult's social environment is also important, including relationship concerns; communication and relationships with children, grandchildren, and aging parents; and caregiver concerns with their own aging or disabled parents.

According to Erikson's (1968, 1982) developmental theory, the primary developmental task of the middle adult years is to achieve generativity (see Chapter 21). *Generativity* is the willingness to care for and guide others. Middle-aged adults can achieve generativity with their own children or other younger people. If middle-aged adults fail to achieve generativity, stagnation occurs. This state is manifested by excessive concern with themselves or destructive behaviour toward their children and the community.

Career Transition. Career changes may occur by choice or as a result of changes in the workplace or society. Middle-aged adults change occupations for a variety of reasons, including limited upward mobility, decreasing availability of jobs, and seeking a more challenging occupation. In some cases, technological advances or other changes force middle-aged adults to seek new jobs. Some middle-aged adults choose not to retire and continue to work as long as they are able to work. Such changes, particularly when unanticipated, may result in stress that can affect health, family relationships, self-concept, and other dimensions. Assessing levels of coping and adaptation to work-related stress and changes is an essential part of your role.

Sexuality. After the departure of their last child from the home, many couples rejuvenate their relationships and find increased marital and sexual satisfaction during middle age. Onset of menopause can affect the sexual health of the middle-aged woman. A woman may desire increased sexual activity because pregnancy is no longer possible. Menopausal women may also experience vaginal dryness and dyspareunia or pain during sexual intercourse (see Chapter 26). During middle age, a man may notice changes in the strength of his erection and a decrease in his ability to experience repeated orgasm. This may result in the use of erectile function-enhancing agents (e.g., sildenafil citrate, tadalafil). Other factors influencing sexuality during this period include work stress, diminished health of

one or both partners, and the use of prescription medications with side effects that may influence sexual desire or functioning (e.g., antihypertensive agents). Both partners may experience stresses related to sexual changes or a conflict between their sexual needs and self-perceptions and social attitudes or expectations. Assessing sexual functioning contributes to identification of potential risks for sexually transmitted infections and adverse health outcomes that can result from erectile function enhancing agents.

Family Types. Psychosocial factors involving the family may include the stresses of singlehood, marital changes, family transition as children leave home, and the care of aging parents.

Singlehood. Many adults older than 35 years have never been married. Many of them have chosen to delay marriage and parenthood. Some single middle-aged adults, however, have chosen to become parents, either biologically or through adoption. Many single middle-aged adults may have no relatives but share a family type of relationship with close friends or work associates. Consequently, some single middle-aged adults may feel isolated during traditional “family” holidays. In times of illness, single adults may have to rely on relatives or friends. Your assessment of single middle-aged adults should include a thorough assessment of psychosocial factors, including the individual’s definition of family and available support systems.

Marital Changes. Marital changes that may occur during middle age include death of a spouse, separation, divorce, and the choice of remarriage or remaining single. If a single, middle-aged adult decides to marry, the stressors of marriage are similar to those for the young adult. A widowed, separated, or divorced patient goes through a period of grief and loss in which it is necessary to adapt to the change in marital status. Normal grieving progresses through a series of phases, and the resolution of grief may take a year or more. You should assess middle-aged adults’ coping with the grief and loss associated with life’s changes (see Chapter 28).

Family Transitions. Departure of the last child from the home may be a stressor. Many parents welcome freedom from child-rearing responsibilities, whereas others feel lonely or without direction because of this change (known as “empty-nest” syndrome). Eventually parents must reassess their marriage, resolve conflicts, and plan for the future. On occasion, this readjustment phase may lead to marital conflicts, separation, and divorce.

Care of Aging Parents. Increasing lifespans have led to increased numbers of older adults in the population. Therefore, greater numbers of middle-aged adults must address the personal and social issues confronting their aging parents, including becoming caregivers for their older parents.

Traditional social expectations between generations in families have changed because of housing, employment, health, and economic realities. Conflicts may arise between middle-aged adults and their older adult parents, who may strive to remain independent. Negotiations and compromises help in defining and resolving problems. You may encounter middle and older adults in the community, in long-term care facilities, and in hospitals. You can help identify the health needs of both groups and can assist the multigenerational family in determining the health and community resources available to them as they make decisions and plans. You should also assess family relationships to determine family members’ perceptions of responsibility and loyalty in relation to caring for older adult members. It is also important to assess environmental

resources (e.g., number of rooms in the house, stair rails, or handrails in bathrooms) needed for adults to care for their older parents.

Health Concerns

Physiological concerns for middle-aged adults include stress, level of wellness, obesity, and the formation of positive health habits. When adults seek health care, your focus on the goal of wellness can guide patients to evaluate health behaviours, lifestyle, and environment. Patients’ health can be undermined by alterable factors such as stress, obesity, tobacco use, excessive alcohol consumption, poor nutrition, and unsafe sexual practices. Drug use, abuse, and misuse may also occur. Attention to these risk factors can increase the quality of life and add years to it.

Stress and Stress Reduction. Middle-aged adults’ perceptions of health and health behaviours are often important factors in maintaining health. Individuals are prone to stress-related illnesses such as heart attacks, hypertension, migraine headaches, ulcers, colitis, autoimmune disease, backache, arthritis, and cancer. Stress levels may also increase as the middle-aged adult tries to balance responsibilities related to employment, family life, care of children, and care of aging parents.

Throughout life, people are exposed to many stressors (see Chapter 29). After these stressors are identified, you and the patient can work together to intervene and modify the stress response. Stress can be reduced in three ways. First, the frequency of stress-producing situations can be minimized. Together, you and the patient identify approaches to prevent stressful situations, such as habituation, change avoidance, time blocking, time management, and environmental modification. Second, stress resistance can be increased by psychophysiological preparation, such as increasing self-esteem, improving assertiveness, redirecting goal alternatives, and reorienting cognitive appraisal. Third, the physiological response to stress can be avoided. You can teach the patient relaxation techniques, imagery, and biofeedback to recondition the patient’s response to stress. Chapter 34 explains these general interventions in greater detail.

Levels of Wellness. You must be able to assess the health status of the middle-aged patient. Such assessment offers direction for planning nursing care and is useful in evaluating the effectiveness of nursing interventions. You can consult Table 23-3, which shows the expected physical assessment findings of the middle-aged adult, and use standard assessment techniques as guides for physical assessment (see Chapter 31).

Obesity. Obesity, defined as having a body mass index of 30 or more, is a health concern for many middle-aged adults. Obesity peaks in middle age. Among Canadian adults, 24% are obese and an additional 36% are overweight (Statistics Canada, 2012a; Tjepkema, 2008). Health consequences of obesity include such conditions as high blood pressure, high blood cholesterol levels, type 2 (non-insulin-dependent) diabetes mellitus, coronary heart disease, osteoarthritis, and obstructive sleep apnea. Continued focus on the goal of wellness can assist patients in evaluating health behaviours and lifestyle that contribute to obesity during the middle adult years. Counselling related to physical activity and nutrition is an important component of the plan of care for overweight and obese patients.

Forming Positive Health Habits. A habit is a person’s usual practice or manner of behaviour. This behaviour pattern

* BOX 23-5 PATIENT TEACHING

Encouraging Positive Health Habits

Objective

- Patient will increase exercise patterns to include three 2 km walks per week to assist in weight loss and to improve cardiopulmonary functions.

Teaching Strategies

- Review with patient the daily work schedule and identify potential times for exercise.
- Inform patient about the effect of exercise on weight control and improved cardiac function.
- Demonstrate how to calculate target heart rate and assess pulse correctly.
- Provide warm-up and cool-down exercises, and demonstrate how to do them.
- Instruct patient about the importance of support shoes for walking exercises.

Evaluation

- Have patient keep log of exercise periods.
- Have patient demonstrate pulse measurement.
- Have patient demonstrate warm-up and cool-down exercises.
- Inspect patient's feet for blisters or sores.

is reinforced by frequent repetition until it becomes the individual's customary way of behaving. Some habits support health, such as exercise, eating a balanced diet, participating in routine screening and diagnostic tests (e.g., laboratory work for cholesterol, mammography), reducing stress, and daily brushing and flossing of teeth. Other habits involve behaviours harmful to health, such as smoking, consuming excessive alcohol, using illegal drugs, or eating foods with little or no nutritional value.

During assessment, you frequently obtain data about patients' positive and negative health behaviours. In the planning, implementation, and evaluation phases, you help the patient maintain habits that protect health and offer healthier alternatives to poor habits.

Health teaching and health counselling are often directed at improving health habits (Box 23-5). The more fully you understand the dynamics of behaviour and habits, the more likely your interventions are to help the patient to achieve or reinforce health-promoting behaviours.

You can coach patients about forming positive health habits. By providing information about how the body functions and how habits are formed and changed, you raise patients' understanding of the impact of behaviour on health. You cannot change patients' habits. Patients have control of and are responsible for their own behaviours. You can explain psychological principles of changing habits and offer information about health risks. Ultimately, however, the patient decides which behaviours will become habits of daily living. Barriers to change exist (Box 23-6). Unless these barriers are minimized or eliminated, it is futile to encourage the patient to take actions that are going to be blocked.

As with adolescents and young adults, you continue educating middle-aged adults about STIs, substance abuse, and accident prevention.

► BOX 23-6

Barriers to Changing Negative Health Habits

External Barriers

- Lack of facilities
- Lack of materials
- Lack of social supports

Internal Barriers

- Lack of knowledge
- Lack of motivation
- Insufficient skills to effect change in health habits
- Undefined short- and long-term goals

Anxiety. Anxiety is a common response to change, conflict, and perceived control of the environment (Austin & Boyd, 2010). Adults often experience anxiety in response to the physiological and psychosocial changes of middle age. Such anxiety can motivate the adult to rethink life goals and can stimulate productivity. For some adults, however, this anxiety precipitates psychosomatic illness and preoccupation with death. Such middle-aged adults view life as being half or more over and think in terms of the time left to live.

Clearly, a life-threatening illness, marital transition, or job stressor increases the anxiety of the patient and family. You may need to use crisis intervention or stress management techniques to help the patient adapt to the changes of the middle adult years (see Chapter 29).

Depression. Depression is a mood disorder that manifests itself in many ways. Although its onset occurs most frequently between the ages of 25 and 44 years, it is common among adults in the middle years and may have many causes (Austin & Boyd, 2010). The risk factors for depression include being female; disappointments or losses at work, at school, or in family relationships; departure of the last child from the home; and family history. The incidence of depression in women is twice that in men.

People experiencing mild depression describe feeling sad, "blue," downcast, "down in the dumps," and tearful. Other symptoms include changes in the amount (not sleeping [insomnia], sleeping too much [hypersomnia]), or quality of sleep (multiple awakenings), irritability, feelings of social disinterest, and decreased alertness. Physical changes such as weight loss or weight gain, headaches, or feelings of fatigue regardless of the amount of rest may also be depressive symptoms. Depression that occurs during the middle years is commonly characterized by moderate to high anxiety and physical complaints. Mood changes and depression are common phenomena during menopause. Depression may be worsened by the abuse of alcohol or other substances. Your assessment of a depressed middle-aged adult includes focused data collection regarding individual and family history of depression, mood changes, cognitive changes, behavioural and social changes, and physical changes. Assessment data should be collected from both the patient and his or her family. Family data may be particularly important, depending on the level of depression being experienced by the middle-aged adult.

Primary Health Care Programs. Primary health care programs for young and middle-aged adults are designed to prevent illness, promote health, and detect disease in the early stages. You can make valuable contributions to the community's health by taking an active part in the planning of screening programs, teaching programs, and support groups for young and middle-aged adults.

* BOX 23-7 CULTURAL ASPECTS OF CARE

All women experience menopause, but the experience itself of menopause is unique for every woman. The culture in which women participate, beginning in early childhood, contributes to how women learn to respond. The experience of menopause for Korean women in Canada has been studied. Elliott et al.'s (2002) findings revealed that although menopause symptoms required management, Korean women considered menopause to be a natural process. They used herbs and maintained healthy diets, as well as used Western medicine, to deal with menopause symptoms.

Implications for Practice

- Be aware of cultural influences that may affect the experience of menopause, and how women seek assistance from health care providers.
- Educational materials that combine Western remedies with traditional approaches may be more easily accepted and utilized.
- Cultural norms and taboos may influence women's willingness to discuss personal issues such as menopause. Information sessions on the topic, or more broadly related to women and aging, should be held in community settings where women might gather and feel comfortable.

Source: Elliott, J., Berman, H., & Kim, S. (2002). A critical ethnography of Korean Canadian women's menopause experience. *Health Care for Women International*, 23(4), 377–388.

Family planning, birthing, and parenting skills are program topics in which adults might be interested. Health screening for diabetes, hypertension, eye disease, and cancer is a good opportunity for you to perform assessment and provide health teaching and health counselling.

Health education programs can promote changes in behaviour and lifestyle. As a health teacher, you offer information that enables the patient to make decisions about health practices. You must be sure that educational programs are culturally appropriate (Box 23-7). Encouraging young to middle adults to adopt more positive health practices during young and middle adulthood may lead to fewer or less complicated health problems during older adulthood. During health counselling, the patient and you should design a plan of action that addresses the patient's health and well-being. Through objective problem solving, you help the patient grow and change.

Acute Care. Acute illnesses and conditions experienced in middle adulthood may be similar to those in young adulthood. Injuries and acute illnesses in middle adulthood, however, may take a longer recovery period because of the slowing of recuperative processes. In addition, acute illnesses and injuries experienced in middle adulthood are more likely to become chronic conditions. The incidence of HIV disease occurs across all age groups and is a consideration for middle-aged adults, as well. Although typically thought of as occurring in earlier age groups, middle-aged adults should be assessed for risk factors and given information to help prevent HIV transmission.

Restorative and Continuing Care. Chronic illnesses such as diabetes mellitus, hypertension, rheumatoid arthritis, chronic obstructive pulmonary disease, or multiple sclerosis may affect the roles and responsibilities assumed by the middle-aged adult. Strained family relationships, modifications in family activities, increased health care tasks, increased

financial stress, the need for housing adaptation, social isolation, medical concerns, and grieving may all result from chronic illness. The degree of disability and the patient's perception of both the illness and the disability determine the extent to which lifestyle changes will occur. A few examples of the problems experienced by patients who develop debilitating chronic illness during adulthood include role reversal, changes in sexual behaviour, and altered self-image. Your assessment of the chronically ill middle-aged adult includes assessment of his or her emotional, physical, social, and spiritual health status and the knowledge base of both the patient and family. This assessment should include the medical course of the illness and the prognosis for the patient. In addition, you determine the coping mechanisms of the patient and family, their adherence to treatment and rehabilitation regimens, and the need for community and social services, along with appropriate referrals.

✦ KEY CONCEPTS

- Adult development involves orderly and sequential changes that adults experience over time.
- Young adults are generally in a stable period of physical development, except for pregnancy-related changes.
- Cognitive development continues throughout the young and middle adult years.
- Emotional health of young adults is correlated with their ability to address and resolve personal and social problems.
- Young adults must choose a career and decide whether to remain single or marry and begin a family.
- Pregnant women need to understand physiological changes occurring during each trimester.
- Psychosocial changes and health concerns during pregnancy and the puerperium period affect the mother and the rest of the family.
- Health promotion interventions are important during the prenatal period and can improve the well-being of the woman and fetus.
- Midlife transition begins when a person becomes aware that physiological and psychosocial changes signify passage to another stage in life.
- Two significant physiological changes of the middle years are menopause in women and changes in sexual response in men.
- Cognitive changes are rare in middle age except in cases of illness or physical trauma.
- Psychosocial changes for middle-aged adults may be related to career transition, sexuality, marital changes, family transition, and care of aging parents.
- Health goals of middle-aged adults commonly involve preventing stress-related illnesses, participating in health assessments, and adopting positive health habits.

✦ CRITICAL THINKING EXERCISES

1. Katya is a 24-year-old woman who smokes two packs of cigarettes per day. She began smoking when she was 14 years old. Katya complains to you at the clinic, "I just can't seem to kick the habit no matter how hard I try." What information do you need to know to assist Katya in quitting smoking?
2. Rohan, 48 years old, married, and the father of 13- and 16-year-old sons, has recently had to assume the responsibility of caring for his 78-year-old mother after she suffered a stroke. Describe your role in assisting Rohan to care for his mother.

❖ REVIEW QUESTIONS

1. Most young adults have completed physical growth by the age of
 1. 18 years
 2. 20 years
 3. 25 years
 4. 30 years
2. Young adults usually have good health. However, it is important to direct health care education in this population toward activities related to
 1. Health promotion
 2. Primary prevention
 3. Secondary prevention
 4. Tertiary prevention
3. When determining what amount of information the individual needs to make decisions about the prescribed course of therapy, you should consider factors that may affect the individual's compliance with the regimen, including educational level, socioeconomic factors, and
 1. Sexuality
 2. Lifestyle
 3. Gender
 4. Motivation and desire to learn
4. A common physiological change in the second trimester of pregnancy is
 1. Morning sickness
 2. Amenorrhea

Older Adulthood

Written by Wendy Duggleby, RN, PhD, AOCN

Based on the original chapter by Karen Korem, RN-BC, MA

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Discuss demographic trends related to older adults in Canada.
- Identify common myths and stereotypes about older adults.
- List the types of community-based and institutional health care services available to older adults.
- Describe the concepts of aging well and quality of life.
- Discuss common developmental tasks of older adults.
- Describe common physiological changes associated with aging.
- Differentiate among delirium, dementia, and depression.
- Discuss issues related to psychosocial changes connected with aging.
- Describe selected health concerns of older adults.
- Identify nursing interventions related to the physiological, cognitive, and psychosocial changes of aging.

The identification of 65 years of age as the start of older adulthood dates back to social reform in Germany in the nineteenth century. The age of 65 years continues to be used as the lower boundary to define older adulthood in demographics and social policy, although many older adults consider themselves to be “middle-aged” well into their 70s (Special Senate Committee on Aging, 2009). In Canada, the Special Senate Committee on Aging (2009) suggests that the term *older person* is the most appropriate term for adults over the age of 65 years. Chronological age may have little relation to the reality of aging for an older adult. Each person ages in his or her own ways according to his or her own schedules and life histories. Even though generalizations are made in this chapter about the aging process and its effect on individuals, every older adult is unique and must be treated as a unique individual by nurses.

The number of older adults in Canada is growing, both absolutely and as a proportion of the total population. Seniors make up the fastest-growing age group in Canada (Human Resources and Skills Development Canada, 2011). In 2011, 5 million adults were older than 65 years in Canada; they represented 14.8% of the population (Statistics Canada, 2012). This number represented an increase of 14.1% since 2006. Geographic variations in the aging population exist across Canada; the proportion of older adults is lowest in Alberta (11.1%) and highest in the four Atlantic provinces (16%) (Statistics Canada, 2012). The number of older adults is expected to increase to

9.8 million (24.5% of the population) by 2036 (Statistics Canada, 2008). Part of that increase is a result of the extension of the average lifespan. In 2005, the average life expectancy at birth for Canadians was 80.4, compared to 70.9 in 1991 (Statistics Canada, 2008). On average, girls born in 2005 can expect to live 4.7 years longer than boys, with a female life expectancy at 82.7 years and male life expectancy at 78 years. Two other factors contribute to the projected increase in the number of older adults: the aging of the baby-boom generation and the growth of the population segment older than 85 years. The baby boomers are the large cohort of adults born between 1946 and 1964. In 2011, the oldest baby boomers reached the age of 65 years and represented the fastest growing age group in Canada. By 2031, all baby boomers will reach the age of 65 and the proportion of seniors in Canada will reach 23%. As baby boomers age, social and health care programs will need to expand to meet their needs, as well as the needs of the second fastest-growing group of adults, those aged 100 years and older (Statistics Canada, 2012). The numbers of centenarians had increased 25.7% since 2006 with a census count of 5826 people in 2011.

The diversity of the population older than 65 years is also projected to increase. Approximately 26.2% of Canadian older adults were born outside of Canada. Most immigrated when young. Between 1995 and 2004, 2% to 4% of immigrants arriving each year were older adults, a number expected to increase as immigration patterns change. Of all immigrant older adults, 96% can speak one or both of Canada's official languages. Of the population older than 65 years, more women than men are unable to speak French or English. In 2001, 5.0% of older women and 3.2% of older men were unable to speak either official language. Currently, older adults make up a small proportion (4%) of Canada's Aboriginal population (Statistics Canada, 2008). However, the number of older Aboriginal people is expected to triple by 2016 as their population ages and lives longer. Caring for older adults from these groups, nurses must account for diversity in cultures, values, and languages. Examples of culturally safe nursing approaches to older adults are respect for preferences in food, music, and religion; attentive listening; use of physical assessment norms appropriate for diverse groups; and asking about personal health practices, family customs, lifestyle preferences, and spiritual resources (Touhy et al., 2012). Chapter 9 provides further information on culturally safe care.

Variability Among Older Adults

The nursing care of older adults poses special challenges because of great variation in their physiological, cognitive, and psychosocial health. Levels of functional ability also vary widely among older adults. The majority of older adults are active and involved members of their communities. A smaller number have lost the ability to care for themselves, are confused or withdrawn, are unable to make decisions concerning their needs, or have a combination of these factors. Most older adults (93%) live in private homes, with only 7% residing in institutions such as nursing homes (Statistics Canada, 2008). Age influences living arrangements: the proportion of older adults living with a spouse decreases with age, the proportion living alone increases with age, and the proportion living in an institution increases with age.

Aging does not inevitably lead to disability and dependence. Most older people remain functionally independent

despite the increasing prevalence of chronic disease. Nursing assessment, a complex and challenging process, can provide valuable clues to the effect a disease or illness is having on a patient's functional status. Chronic conditions add to the complexity of assessment and care of the older adult. Approximately 91% of older adults report one or more chronic conditions; arthritis, hypertension, heart disease, vision impairment, and diabetes mellitus are the most common conditions in non-institutionalized older adults (Statistics Canada, 2008). These chronic conditions impose limitations on activities: slightly more than 22% of adults 65 to 74 years of age and nearly 50% 85 years or older report some limitations in activities.

The physical, cognitive, and psychosocial aspects of aging are closely related. For the older adult, a reduced ability to respond to stress, the experience of multiple losses, and the physical changes associated with normal aging may combine to increase the risk for illness and functional deterioration. Although the interaction of these physical and psychosocial factors can be serious, you should not assume that all older adults have signs, symptoms, or behaviours representing disease and decline or that these are the only items to be assessed. An older adult's strengths and abilities must also be identified during the assessment.

Terminology

As the number of older adults increases, the specialty of gerontological nursing is gaining in importance. Several terms are used, at times interchangeably, to describe this specialty (Meiner & Leuckenotte, 2006):

- **Geriatrics** is the branch of medicine that deals with physiological and psychological aspects of aging and with diagnosis and treatment of diseases affecting older adults.
- **Gerontology** is the study of all aspects of the aging process and its consequences.
- **Gerontological nursing** is concerned with assessment of the health and functional status of older adults; diagnosis, planning, and implementing health care and services to meet the identified needs; and evaluating the effectiveness of such care. This is the term most often used by nurses specializing in this field.
- **Gerontic nursing**, a seldom-used term that is gaining popularity, is the art and practice of nurturing, caring for, and comforting older patients, rather than merely the treatment of disease.

Myths and Stereotypes

Despite ongoing research in the field of gerontology, false beliefs and myths about older adults persist. These stereotypes include beliefs about the physical and psychosocial characteristics and the lifestyles of older adults. However, negative stereotypes may adversely affect access to and the quality of the care provided to older patients (Kagan, 2008). Nurses, although personally susceptible to the myths and stereotypes held by society, have the responsibility to dispel the myths and replace the stereotypes with accurate information.

Older adults are sometimes stereotyped as ill and disabled. However, although many experience chronic conditions or have at least one disability that limits performance of activities of daily living (ADLs), only 23% of older adults describe their health as poor or fair (Statistics Canada, 2008). Other common misconceptions are that older adults are generally not

interested in sex and that any interest in sexual activities is abnormal and should be discouraged. However, many older adults report continued enjoyment of sexual relationships.

Some people believe that older adults are forgetful, confused, rigid, bored, unfriendly, and unable to understand and learn new information. However, centenarians, the oldest of the old, are described as having an optimistic outlook on life, good memories, broad social contacts and interests, and tolerance for others (Touhy et al., 2012). Although the process of learning may be affected by age-related changes in vision or hearing or by reduced energy and endurance, older adults are lifelong learners. You should use teaching techniques that compensate for sensory changes, provide additional time for remembering and responding, and present concrete rather than abstract material to facilitate learning by older adults. Other effective teaching techniques draw from older adults' past experiences and correspond to their identified interests rather than to the content areas believed important by the health care provider. Box 24-1 presents additional teaching strategies that you can use to address the learning needs of older adults.

In a society that values attractiveness, energy, and youth, these myths and stereotypes lead to the undervaluing of older adults. Some people believe that older adults are unattractive and become worthless to society after they leave the

* BOX 24-1 FOCUS ON OLDER ADULTS

Older Adult Learning Needs Teaching Strategies

- Make sure the patient is ready to learn before you try to teach him or her. Watch for clues that would indicate that the patient is preoccupied or too anxious to comprehend the material.
- Sit facing the patient so that he or she can watch your lip movements and facial expressions.
- Speak slowly.
- Keep your tone of voice low; older adults can hear low-frequency sounds better than high-frequency sounds.
- Give the patient enough time to respond because older adults' reaction times may be longer than those of younger people.
- To help the patient concentrate, focus on a single topic.
- Keep environmental distractions to a minimum.
- With permission of the patient, invite another member of the household to join the discussion.
- Use auditory, visual, and tactile cues to enhance learning and help the patient remember information.
- Ask for feedback to ensure that the information has been understood.
- Refer to the patient's past experience; connect new learning to that already learned.
- Compensate for physical discomfort and sensory alterations if necessary.
- Support a positive self-image in the learner.
- Use creative teaching strategies.
- Respond to identified interests of learners.
- Emphasize and integrate emotional and personal values in the acquisition of skills and ideas.

workforce. Others consider the knowledge and experience of older adults to be too old-fashioned to have any current value. These notions underlie the concept of **ageism**, which is discrimination against people because of increasing age, just as racism and sexism are discrimination based on skin colour and gender, respectively. Ageism has the potential to undermine the self-confidence of older adults, limit their access to care, and distort caregivers' understanding of the uniqueness of each older adult (Special Senate Committee on Aging, 2009). A society that values the contribution and wisdom of the older adult helps them to maintain decision making and function to their greatest ability. The Canadian Special Senate Committee on Aging (2009) has concluded that ageism in Canada is pervasive and subtle. Immediate action is needed to combat ageism.

Nurses' Attitudes Toward Older Adults

It is important for you to assess your attitudes toward older adults, your own aging, and the aging of your family, friends, and older adults. Your attitudes toward older adults result partly from personal experiences with older adults' education, employment experiences, attitudes of co-workers and employers, and your own age. Cultivation of positive attitudes toward older adults and specialized knowledge about aging and the health care needs of older adults are priorities for nurses.

Positive attitudes are based in part on a realistic portrayal of the characteristics and health care needs of older adults. In the past, negative attitudes about aging have contributed to the persistence of stereotypes of older adults as dependent and less attractive than younger persons. Health care providers, under the influence of these attitudes, often lacked respect for older persons and ignored the opportunity to actively involve them in care decisions and activities. At times, hospitals and long-term care facilities have treated older adults as objects to be acted upon rather than as independent, dignified adults. The time has come for all nurses to recognize and address ageism by questioning prevailing negative attitudes and stereotypes and advocating for older adults in all care settings.

Theories of Aging

Various theorists have attempted to describe the complex biopsychosocial process of aging. Although many theories have been developed, no single universally accepted theory predicts and explains the complexities of the aging process. You must be aware of the scientific attempts to explain the aging process and the concepts included in the theories. Although the theories are in various stages of development and have limitations, you can use them to increase your understanding of the phenomena affecting the health and well-being of older adults.

The biological theories of aging are categorized as either stochastic theories or nonstochastic theories. **Stochastic theories** view aging as the result of random cellular damage over time. The accumulated damage leads to the physical changes characteristic of the aging process. According to the **nonstochastic theories**, genetically programmed physiological mechanisms within the body control the process of aging.

Psychosocial theories of aging attempt to explain changes in behaviour, roles, and relationships that come with aging. As with biological theories of aging, no single psychosocial theory is universally accepted. The psychosocial theories also reflect the values held by the theorist and society at the time the

theory was first articulated. The three classic psychosocial theories of aging are disengagement theory, activity theory, and continuity theory. According to disengagement theory, the oldest psychosocial theory, aging individuals withdraw from customary roles and engage in more introspective, self-focused activities as society disengages from them (Cummings & Henry, 1961). In the activity theory, unlike the disengagement theory, the continuation of activities performed during middle age is considered necessary for successful aging (Lemon et al., 1972). According to continuity theory or developmental theory (Neugarten, 1964), personality remains the same and behaviour becomes more predictable as people age. Personality and behaviour patterns developed during a lifetime determine the degree of engagement and activity in older adulthood. Newer psychosocial theories, such as gerotranscendence theory (Tornstam, 2003), suggest that older adults deal with the aging process by focusing on others and existential issues such as spirituality rather than their own limitations.

Critics suggest, however, that all psychosocial theories either fail in some measure to consider the many factors that affect an individual's response to the aging process or address those factors in a simplistic manner. Biologically, psychosocially, and spiritually, each individual ages in a unique way.

Developmental Tasks for Older Adults

Theories of aging are closely linked to the concept of developmental tasks appropriate for distinct stages of life. Although no two individuals age in the same way, either biologically or psychosocially, frameworks outlining developmentally appropriate tasks for older adults have been developed. Seven developmental tasks of the older adults are listed in Box 24-2.

These developmental tasks are common to many older adults and are associated with varying degrees of change and loss. The more common losses involve health, significant others, a sense of being useful, socialization, income, and independent living. The ways that older adults adjust to the changes of aging are highly individualized. For some, adaptation and adjustment are relatively easy. For others, coping with the changes caused by aging may require the assistance of family, friends, and health care providers. You must be sensitive to the effect of such losses on older adults and their families and be prepared to offer support.

Older adults must also adjust to the physical changes that accompany aging. The extent and timing of these changes vary from individual to individual, but as body systems age, changes occur in appearance and functioning. These changes are not associated with a disease but are normal changes. The presence of disease may alter the timing of the changes or their

impact on daily life. Structural and functional changes associated with aging are described in "Physiological Changes."

Aging Well and Quality of Life

More recently, theories of successful aging and developmental tasks have been integrated into the concept of aging well or active aging (Chapman, 2005). Older adults are considered to be "**aging well**" when they are achieving self-integration of all aspects of growing older. Faced with the changes that come with aging, older adults must find ways to maintain their quality of life. Existential issues and relationships are important aspects of quality of life for older adults (Register & Herman, 2010). However, the definition of quality of life varies from person to person. You must listen to what an older adult considers to be most important, rather than making assumptions about that individual's priorities. Together, you and the older adult may set objectives for maintaining quality of life, whether quality of life is defined as maintenance of social relationships, continuing to live alone, or continuing activities such as driving or gardening or dancing (Figure 24-1).

Community-Based and Institutional Health Care Services

You may encounter older adults in a wide variety of community-based and institutional health care settings. Outside of the acute care hospital setting, you and other nurses may care for older adults in private homes and apartments, adult day care centres, assisted-living facilities (also known as *supportive housing*), long-term care facilities, and hospices.

Figure 24-1 Older adults engage in many activities that help them to maintain their quality of life.

► BOX 24-2

Developmental Tasks for Older Adults

- Adjusting to decreasing health and physical strength
- Adjusting to retirement and reduced or fixed income
- Adjusting to the death of a spouse
- Accepting one's self as an aging person
- Maintaining satisfactory living arrangements
- Redefining relationships with adult children
- Finding ways to maintain quality of life

Adapted from Erikson, E. H., Erikson, J. M., & Kivnick, H. Q. (1986). *Vital involvement in old age: The experience of old age in our time*. New York: W. W. Norton.

Long-term care facilities provide accommodations, 24-hour nursing care, and support services for people who cannot care for themselves at home but do not need hospital care. Assisted-living facilities are designed for residents who need only minimal to moderate care. Residents live independently in their own apartments and are provided with support services such as homemaking or personal care. Some assisted-living facilities are small group homes where residents share common eating and living areas. In some provinces, personal care homes are offered as a type of assisted-living facility. A **personal care home** is a private business that provides accommodation, meals, and supervision or assistance with personal care in a familylike atmosphere. Nursing services are not usually included in assisted-living facilities. Palliative care facilities such as hospices focus on providing care for adults who are dying. They can be publicly or privately funded.

You can also assist older adults and their families by providing information and answering questions as they make choices among care options. During the decision-making period, the actual move from a private home to an assisted-living or long-term care facility, and the time after the move, your role is to support the older adult and the family. You can provide information about the selection of a good assisted-living or long-term care facility (Box 24-3).

Canadian seniors, because of their changing health status, will need different types of care options during their life. These include health care and social services (Special Senate Committee on Aging, 2009). You, as a nurse, will have an important role in helping older adults transition between facilities. This role involves providing information and assisting them in finding the appropriate care options.

* BOX 24-3 FOCUS ON OLDER ADULTS

This information will help older adults in choosing housing options that are appropriate for their personal situations. Here are some factors for them to consider:

- **Needs:** Depending on how much support they need, different types of facilities offer different levels of support.
- **Preferences:** Each type of facility has advantages and disadvantages. Consider what is most important to the older adult when deciding.
- **Support Network:** How much support do they have from family and friends? This will determine the type of facility they need.
- **Eligibility:** In Canada, publicly funded facilities have eligibility criteria. Find out what they are so older adults know what options they have.
- **Availability:** Where the older adults live may determine if there is a facility that is available or if it has openings.
- **Finances:** Check out the cost of the facility to determine if the patient is able to pay the costs or needs to consider other options.
- **Timing:** At times the older adult will have to make a decision quickly. This situation can determine the options available to the older adult.

Adapted from the Government of Ontario. (2011). *Seniors care: Things to consider*. Toronto: Queen's Printer for Ontario. Retrieved from http://www.health.gov.on.ca/english/public/program/lc/tc4_consider.html

Assessing the Needs of Older Adults

Gerontological nursing offers creative approaches for maximizing the potential of older adults. The standards of practice of the Canadian Gerontological Nursing Association (2010) were developed to define the uniqueness and scope of gerontological nursing practice, which includes functions such as assessment. With comprehensive assessment information regarding an older person's strengths, resources, and limitations, you and the older adult can identify needs and problems and select interventions that maintain their physical abilities and create an environment for psychosocial and spiritual well-being. A thorough assessment requires you to actively engage older adults and provide them with enough time to share important information about their health. You should assess for changes in physiology, cognition, and psychosocial behaviour.

Nursing assessment must take into account five key points to ensure an age-specific approach: (1) the interrelation between physical and psychosocial aspects of aging, (2) the effects of disease and disability on functional status, (3) the decreased efficiency of homeostatic mechanisms, (4) the lack of standards for health and illness norms, and (5) altered manifestations of and responses to specific disease (Meiner & Leukenotte, 2006). Obtaining a comprehensive assessment of an older adult often takes more time than does an assessment of a younger adult because of the longer life and medical history and the potential complexity of that history. By planning to spend extra time with the assessment, you and an older adult are less likely to feel rushed. During the physical examination, you may find it necessary to allow rest periods or to conduct the assessment in several sessions because of the reduced energy and limited endurance experienced by some frail older adults.

Sensory changes may also affect data gathering. Your choice of communication techniques is influenced by any visual or hearing impairment experienced by the older adult. If older adults are unable to understand your visual or auditory cues, assessment data may be inaccurate or misleading. For example, if an older adult has difficulty hearing your questions, his or her responses may be inappropriate, and you may wrongly believe that he or she is confused. You can use the following communication techniques with an older adult who has a visual impairment:

- Sit or stand in front of the older adult in full view.
- Face the older adult while speaking; do not cover your mouth.
- Provide diffuse, bright, nonglare lighting.
- Encourage older adults with assistive devices such as glasses or magnifiers to use them.

You can use the following techniques with an older adult who has a hearing impairment:

- Speak directly to the older adult do not cover your mouth.
- Speak in clear, low-pitched tones at a moderate rate and volume.
- Reduce background noises; move to a quiet, private room.
- Ask whether they have a "good ear," and speak toward that ear.
- Encourage older adults to use assistive devices such as hearing aids or "microphone plus earphones."
- Make sure the hearing aid is working properly (check the battery, check that the hearing aid is turned on, adjust volume controls).
- Check the ear canal for cerumen impaction.

Memory deficits, if present, will affect the accuracy and completeness of the data collected. Information contributed by a family member or other caregiver, such as a history of allergies and documentation of immunizations, may be necessary to supplement the older adult's recollection of past medical events and information. You must use tact when involving another adult in the assessment interview with an older adult. The additional adult supplements the answers of the older person with their consent, but the older adult remains the focus of the interview.

Interpreters or cultural brokers must be present when an older adult does not speak your language. The spoken word must be interpreted within the context of the older adult's culture. To ensure culturally safe means of communication during assessment, (1) identify how the older adult wishes to be addressed (use culturally appropriate titles); (2) assess the health-related beliefs and practices of the older adult; and (3) know the beliefs and practices of the older adult's culture group with regard to spatial requirements, eye contact, and touch, and use them to establish rapport.

In older patients, signs and symptoms of diseases and laboratory values may be different from those in younger patients; the classic signs and symptoms of diseases may be absent, blunted, or atypical in older adults (Meiner & Leukenotte, 2006). These differences may result from age-related changes in organ systems and homeostatic mechanisms, from progressive loss of physiological and functional reserves, or from coexisting acute or chronic conditions. As a result, for example, an older adult with a urinary tract infection may present with confusion, loss of appetite, weakness, dizziness, or fatigue instead of fever, dysuria, frequency, or urgency; an older adult with pneumonia may have tachycardia, tachypnea, and confusion without the more common symptoms of fever and productive cough; and instead of substernal chest pain and diaphoresis, an older adult with a myocardial infarction may experience epigastric discomfort, restlessness, hypotension, confusion, or referred or no pain. Variations from the usual norms for laboratory values may result from age-related changes in cardiac, pulmonary, renal, and metabolic function (Wold, 2008). Examples of laboratory values that may be increased by these changes include, but are not limited to, levels of alkaline phosphatase, serum cholesterol, triglycerides, serum glucose (postprandial), and serum uric acid. Examples of laboratory values that may be decreased by the aging process include, but are not limited to, levels of serum calcium and serum creatine kinase, as well as creatinine clearance.

It is important to recognize the early indicators of acute illness in older adults: change in mental status, falls, dehydration, decrease in appetite, loss of function, dizziness, and incontinence. Two key principles of providing age-appropriate nursing care are timely detection of these cardinal signs of illness and a focus on finding underlying causes so that treatment can begin (Box 24-4). Attention is often not paid to underlying causes as a result of mistaken assumptions about normal aging (Wold, 2008). Many health challenges can coexist, which adds to the difficulty in isolating the causes of symptoms. Mental status commonly changes as a result of disease and psychological issues, but more often in relation to drug toxicity or adverse drug events. A fall is a complex event, and careful investigation is necessary to find out whether it has environmental causes or is the symptom of a new-onset illness; such illnesses include cardiac, respiratory, musculoskeletal, neurological, urological, and sensory disorders. Dehydration is

► BOX 24-4

Examples of Indicators of Acute Illness in Different Settings

Hospital

- Confusion is not inevitable. Look for neurological events, new medication, or the presence of risk factors for delirium.
- Many hospitalized older adults suffer from chronic dehydration accelerated by acute illness.
- Not all older adults have fevers with infection. Symptoms may include increased respiratory rate, falls, incontinence, or confusion.

Nursing Home

- Health care providers often undertreat pain in older adults, especially those with dementia. Look for nonverbal cues such as grimacing or resistance to care.
- Decline in functional ability (even a minor one, such as the inability to sit upright in a chair) is a signal of new illness.
- Residents with less muscle mass—both frail and obese adults—are at heightened risk for toxicity from protein-binding drugs such as phenytoin (Dilantin) and warfarin (Coumadin).
- Urinary or fecal incontinence is often a sign of the onset of a new illness.

Ambulatory Care

- Complaints of fatigue or decreased ability to perform usual activities are signs of anemia, thyroid problems, depression, or neurological or cardiac problems.
- Severe gastrointestinal problems in older adults do not always manifest with the same acute symptoms seen in younger patients. Ask about constipation, cramping sensations, and changes in bowel habits.
- Older adults reporting increased dyspnea and confusion, especially those with a cardiac history, need to go to the emergency department; these are the most common manifestations of myocardial infarction in this population.
- Depression is common among older adults with chronic illnesses. Watch for lack of interest in formerly pleasurable activities, and be alert to significant personal losses or changes in role or home life.

Home Care

- Investigate all falls, focusing on balance, gait, and neurological issues.
- Monitor older adults with late-stage heart disease for loss of appetite, which is an early symptom of impending heart failure.
- Monitor for drug-drug interactions in older patients who are seeing more than one health care provider and taking multiple medications.

Adapted from Amella, E. J. (2006). Presentation of illness in older adults. If you know what you are looking for, think again. *AORN Journal*, 83(2), 372–389.

common in older adults because the thirst response is reduced, which results in less water intake, and because less free water is available as a consequence of decreased muscle mass. Vomiting and diarrhea can accompany the onset of an acute illness, and older adults are then at risk for further dehydration. Decrease in appetite is a common symptom with the onset of pneumonia, heart failure, and urinary tract infection. Loss of functional ability occurs either in a subtle manner over time or suddenly, depending on the underlying cause. Thyroid disease, infection, cardiac or pulmonary conditions, metabolic disturbances, and anemia are common causes of functional decline, so you need to identify them early and notify care providers

so that proper treatment can be initiated. Dizziness is a common sign of various acute illnesses, including anemia, arrhythmia, infection, myocardial infarction, stroke, and brain tumour. New-onset urinary incontinence in an older adult is often associated with a urinary tract infection, but it can also be a symptom of an electrolyte abnormality or adverse drug event.

Physiological Changes

Perception of well-being can define quality of life. Understanding a patient's perceptions about health status is essential for the accurate assessment and development of clinically relevant interventions. Older adults' concepts of health generally depend on personal perceptions of functional ability. Therefore, older adults engaged in ADLs usually consider themselves healthy, whereas those whose activities are limited by physical, emotional, or social impairments may perceive themselves as ill.

Many observed physiological changes in older adults are called "normal." Finding such changes during an assessment is not unexpected. These physiological changes are not always pathological processes, but they may make older adults more vulnerable to some common clinical conditions and diseases. Some older adults experience all of these physiological changes, and others experience only a few. The body changes continuously with age, and specific effects on particular older adults depend on health, lifestyle, stressors, and environmental conditions. You should know about these commonly experienced changes in order to provide appropriate care for older adults and to assist with adaptation to the changes. Common physiological changes are summarized in Table 24-1.

General Survey. The general survey occurs during your initial encounter with an older adult and includes a quick, but careful, head-to-toe scan of the patient, which you should document in a concise description. An initial inspection of an older adult might reveal whether eye contact and facial expression are appropriate to the situation, as well as common aging changes such as facial wrinkles, grey hair, loss of body mass in the extremities, and an increase of body mass in the trunk.

Integumentary System. With aging, the skin loses resilience and moisture. The epithelial layer thins, and elastic collagen fibres shrink and become rigid. Wrinkles of the face and neck reflect lifelong patterns of muscle activity and facial expressions, the pull of gravity on tissue, and diminished elasticity.

Spots and lesions may also be present on the skin. Smooth, brown, irregularly shaped spots ("age spots," or senile lentigo) initially appear on the backs of the hands and on forearms. Small, round, red or brown cherry angiomas may be found on the trunk. Seborrhic lesions or keratoses may appear as irregular, round or oval, brown, watery lesions. Years of sun exposure contribute to the aging of the skin and may lead to premalignant and malignant lesions. In examining skin lesions, you must rule out three malignancies related to sun exposure: melanoma, basal cell carcinoma, and squamous cell carcinoma (see Chapter 31).

Head and Neck. The facial features of older adults become more pronounced as a result of loss of subcutaneous fat and skin elasticity. Facial features may appear asymmetrical because of missing teeth or improperly fitting dentures. In addition, common vocal changes include a rise in pitch and a loss of power and range.

Visual acuity declines with age. This may be the result of retinal damage, reduced pupil size, development of opacities

in the lens, or loss of lens elasticity. Presbyopia (gradual decline in the ability to focus on close objects) is common in older adults. The ability to see in darkness is reduced, and adaptation to abrupt changes from dark areas to light areas (and the reverse) is slower. Ambient lighting (soft, indirect light that usually illuminates the entire room) is generally the best lighting for older adults. However, older adults also have increased sensitivity to the effects of glare, and interventions to increase ambient light should not increase glare. Changes in colour vision and discoloration of the lens make it difficult to distinguish between blues and greens and among pastel shades.

Auditory changes are often subtle. The earliest losses of hearing acuity may be ignored until friends and family members comment on it. Presbycusis, a common age-related change in auditory acuity, is a decrease in the ability to hear high-pitched sounds and sibilant consonants such as "s," "sh," and "ch." Before you assume that presbycusis is present, you must inspect the patient's external auditory canal for the presence of cerumen (earwax). Impacted cerumen is an easily treated cause of diminished hearing acuity.

Taste buds atrophy and lose sensitivity. Older adults are less able to discern among salty, sweet, sour, and bitter tastes. The sense of smell is also decreased, which further reduces the sense of taste. Salivary secretion is reduced as well.

Thorax and Lungs. Because of changes in the musculoskeletal system, the configuration of the thorax sometimes changes. After the age of 55 years, respiratory muscle strength begins to decrease. The anteroposterior diameter of the thorax increases. The incidence of osteoporosis is increased in older adults, and vertebral changes caused by osteoporosis can lead to dorsal kyphosis, the curvature of the thoracic spine sometimes called "dowager's hump." Calcification of the costal cartilage can cause decreased mobility of the ribs. The chest wall gradually becomes stiffer. Lung expansion decreases. If kyphosis or chronic obstructive lung disease is present, breath sounds are distant.

Heart and Vascular System. Decreased contractile strength of the myocardium results in decreased cardiac output. This is significant when an older adult experiences stress from anxiety, excitement, illness, or strenuous activity. The body tries to compensate for decreased cardiac output by increasing the heart rate during exercise. However, after exercise, it takes longer for an older adult's rate to return to baseline.

Systolic or diastolic blood pressure, or both, may be abnormally elevated. More than 50% of older adults have systolic hypertension (systolic pressure >140 mm Hg) or diastolic hypertension (diastolic pressure >90 mm Hg). Although it is a common chronic condition, hypertension is not a normal aging change; it predisposes older adults to heart failure, stroke, renal failure, coronary heart disease, and peripheral vascular disease.

Peripheral pulses become frequently weaker in the lower extremities, although they are still palpable. Older adults may report that their lower extremities are cold, particularly at night. Changes in the peripheral pulses in the upper extremities are less common.

Breasts. In older women, the breasts sag as a result of decreased muscle mass, tone, and elasticity. Atrophy of glandular tissue, coupled with more fat deposits, causes breasts to become slightly smaller, less dense, and less nodular. Gynecomastia (enlarged breasts in men) may be caused by medication side effects, hormonal changes, or obesity. Both older men and women are at risk for breast cancer.

► TABLE 24-1 Common Physiological Changes With Aging

Anatomical Part	Common Changes	Anatomical Part	Common Changes
System		Sensory	
Integument	Loss of skin elasticity (resulting in wrinkles, sagging, easily tears) Decrease in adipose tissue Decrease efficiency of sweat glands Decreased secretions of sebaceous glands, and increased dryness of the skin	Eyes	Decreased ability to focus on near objects (presbyopia) Difficulty adjusting to changes from light to dark Yellowing of the lens Altered perception of colours Increased sensitivity to glare Smaller pupils
Respiratory	Decreased cough reflex Decreased removal of mucus, dust, irritants from airways (decreased cilia) Inefficiency of gas exchange Increased chest wall rigidity Fewer alveoli, increased airway resistance Increased risk of respiratory infections	Ears	Loss of ability to hear high-frequency tones (presbycusis) Thickening of tympanic membrane Sclerosis of inner ear Possible buildup of cerumen (earwax)
Cardiovascular	Thickening of blood vessel walls Increased peripheral resistance Loss of vessel elasticity Lower cardiac output Decreased baroreceptor sensitivity Increased pulmonary vascular tension Increased systolic blood pressure Decreased peripheral circulation	Taste	Often diminished; possibly fewer taste buds
Gastrointestinal	Periodontal disease Loss of teeth Decrease in saliva, gastric secretions, and pancreatic enzymes Changes in smooth muscle, with decreased esophageal peristalsis and small intestinal motility	Smell	Often diminished
Musculoskeletal	Decreased muscle mass and strength Decalcification of bones Degenerative joint changes Dehydration of intervertebral disks (decreased height)	Touch	Decreased skin receptors
Neurological	Degeneration of nerve cells Decrease in neurotransmitters Decrease in rate of conduction of impulses	Proprioception	Decreased awareness of body positioning in space
		Genitourinary	Decreased ability to respond to water load deficits Decreased renal blood flow Decreased bladder capacity Men: enlargement of prostate Women: reduced sphincter tone
		Reproductive	
		Female	Decreased estrogen production Degeneration of ovaries Atrophy of vagina, uterus, breasts
		Male	Diminished sperm count Smaller testes Less firm and slower erections
		Endocrine	
		General	Alteration in hormone production with decreased ability to respond to stress
		Thyroid Thymus	Decreased secretion Involution of thymus gland
		Cortisols, glucocorticoids	Increased levels of anti-inflammatory hormones
		Pancreas	Increased fibrosis, decreased secretion of enzymes and hormones

Data from Touhy, T. A., Jett, K. F., Boscart, V., & McCleary, L. (2012). *Ebersole & Hess' geriatric nursing and healthy aging* (1st Cdn. ed.). Toronto: Elsevier Canada.

Gastrointestinal System and Abdomen. Aging leads to an increase in the amount of fatty tissue in the trunk. As a result, the abdomen increases in size. Because muscle tone and elasticity decrease, the abdomen also becomes more protuberant. Gastrointestinal function changes include a slowing of peristalsis and alterations in secretions. Older adults may experience these changes as the development of intolerance to certain foods and as discomfort caused by delayed gastric emptying. Alterations in the lower gastrointestinal tract may lead to constipation, flatulence, or diarrhea.

Reproductive System. Changes in the structure and function of the reproductive system occur as the result of hormonal alterations. Menopause is related to a reduced responsiveness of the ovaries to pituitary hormones and a resultant

decrease in estrogen and progesterone levels. In men, fertility does not cease in association with aging. Spermatogenesis begins to decline during the fourth decade but continues into the ninth. The changes in reproductive structure and function, however, do not affect libido. Sexual activity can become less frequent as a result of illness, death of a sexual partner, decreased socialization, or loss of sexual interest.

Urinary System. Hypertrophy of the prostate gland may develop in older men. The gland enlarges, and pressure is displaced to the neck of the bladder. As a result, urinary retention, frequency, incontinence, and urinary tract infections may occur. In addition, prostatic hypertrophy can result in difficulty initiating voiding and maintaining a urinary stream. Benign prostatic hypertrophy must be distinguished from

cancer of the prostate. Cancer of the prostate is the malignancy most frequently diagnosed in men older than 70 years, and it results in the death of 1 per 27 men in whom it is diagnosed (Canadian Cancer Society, 2008).

Urinary incontinence is an abnormal condition, although it is experienced by 50% of women older than 45 years (Canadian Continence Foundation, 2007). The prevalence of incontinence increases with age. Older women, particularly those who have borne children, can experience stress incontinence, an involuntary release of urine that occurs when they cough, sneeze, or lift an object. This type of incontinence results from a weakening of perineal and bladder muscles. Other types of urinary incontinence are transient, urge, overflow, functional, reflex, and mixed incontinence (see Chapter 43). The Registered Nurses' Association of Ontario (RNAO) (2005b) recommended assessing risk factors for urinary incontinence, which include individual factors (fluid intake, medications, functional ability, and medical history) and environmental factors.

Musculoskeletal System. With aging, muscle fibres are reduced in size. Muscle strength diminishes in proportion to the decline in muscle mass. Bone mass also declines. Older adults who exercise regularly do not lose as much bone and muscle mass or muscle tone as those who are inactive. Of Canadian women older than 50 years, 25% have osteoporosis (Osteoporosis Canada, 2008). Women who maintain calcium intake throughout life and into menopause have less bone demineralization than women with low calcium intake. Older men with poor nutrition and decreased mobility are also at risk for demineralization. One in eight men in Canada has osteoporosis.

Neurological System. The decrease in the number of neurons in the nervous system that begins in the middle of the second decade can lead to changes such as the sensory disturbances described earlier. In addition, older adults may experience a decreased sense of balance or uncoordinated motor responses. Older adults frequently report alterations in the quality and the quantity of sleep, including difficulty falling asleep, difficulty staying asleep, difficulty falling asleep again after waking during the night, waking too early in the morning, and excessive daytime napping (see Chapter 40).

Functional Changes

Declines in physical, psychological, cognitive, and social function that can occur with aging are usually linked to illness or disease and its degree of chronicity. However, the complex relationship among all of these areas ultimately influences an older adult's functional abilities and overall well-being. It is difficult for older adults to accept the changes that occur in all the areas of their lives, which in turn have a profound effect on function. Some older adults deny the changes and continue to expect the same performance from themselves regardless of age. Conversely, some overemphasize these changes and prematurely limit their activities and involvement in life. Also, the fear of becoming dependent is overwhelming for an older adult who is experiencing functional decline as a result of aging. You should educate older adults to promote understanding of age-related changes, appropriate lifestyle adjustments, and effective coping. Factors that promote the highest level of function in all the areas include a healthy, well-balanced diet; paced and appropriate activity; regularly scheduled visits with a health care provider; regular participation in meaningful activities; use of stress management techniques; and avoidance of alcohol, tobacco, and illicit drugs. *Functional status* in older adults ordinarily refers to the capacity and safe

performance of ADLs and is a sensitive indicator of health or illness in older adults. ADLs are essential to independent living; therefore, you must carefully assess whether an older adult has changed the way in which he or she completes these tasks. In fact, a sudden change in function, as evidenced by a decline or change in an older adult's ability to perform any one or combination of ADLs, is often a sign of the onset of an acute illness, pain, or worsening of a chronic problem. Pneumonia, urinary tract infection, dehydration, electrolyte disturbances, and delirium are examples of acute illnesses that may manifest as a change in function. Worsening of chronic conditions such as diabetes, cardiovascular disease, and chronic lung disease can also manifest as a change in function.

Various health care providers in a range of different settings are able to perform a functional assessment. Several standardized functional assessment tools are widely available; an online collection of tools is available at <http://www.geronurseonline.org>. When you identify a decline in function, focus nursing interventions on maintaining, restoring, and maximizing the older adult's functional status so that he or she can maintain independence while preserving dignity.

Cognitive Changes

A common misconception about aging is that cognitive impairments are widespread among older adults. Forgetfulness is not an expected consequence of aging. Older adults often fear that they are, or soon will be, cognitively impaired. Younger persons often assume that older adults are confused and no longer able to handle their affairs. Structural and physiological changes within the brain—such as reduction in the number of cells, deposition of lipofuscin and amyloid in cells, and change in neurotransmitter levels—are normal with aging and are observed in older adults whether they do or do not have cognitive impairment. Symptoms of cognitive impairment such as disorientation, loss of language skills, loss of the ability to calculate, and poor judgement are not normal aging changes. When you identify these changes during the assessment, you must further investigate the underlying causes.

The three common conditions affecting cognition are delirium, dementia, and depression (Table 24-2). You may find that distinguishing among these three conditions is challenging but essential for selecting appropriate nursing interventions. The RNAO (2010) published revised best practice guidelines to screen for delirium, dementia, and depression in older adults. Appropriate nursing interventions specifically address the cause of the cognitive impairment.

Delirium. Delirium, or acute confusional state, is a potentially reversible cognitive impairment that often has a physiological cause. Physiological causes of delirium include, but are not limited to, electrolyte imbalances, cerebral anoxia, hypoglycemia, medications, drug effects, tumours, subdural hematomas, pain, infection, and cerebrovascular infection, infarction, or hemorrhage. Delirium in older adults sometimes accompanies systemic infections and may be the presenting symptom for pneumonia or urinary tract infection. Delirium may also have environmental causes (e.g., sensory deprivation, unfamiliarity with surroundings) or psychosocial causes (e.g., emotional distress, pain). Although delirium may occur in any setting, an older adult in the acute care setting is especially at risk because of predisposing factors (physiological, psychosocial, and environmental) in combination with the medical condition that led to the hospital admission.

Delirium is characterized by fluctuations in cognition, mood, attention, arousal, and self-awareness. Other signs may

► **TABLE 24-2** A Comparison of the Clinical Features of Delirium, Dementia, and Depression

Clinical Feature	Delirium	Dementia	Depression
Onset	Acute or subacute, depending on cause; often occurs at twilight or in darkness	Chronic and generally insidious, depending on cause	Chronic and generally insidious, depending on cause
Course	Short episodes; diurnal fluctuations in symptoms; worse at night, in darkness, and on awakening	Long episodes; no diurnal effects; symptoms progressive and yet relatively stable over time	Diurnal effects; typically worse in the morning; fluctuations situational but less so than those of delirium
Progression	Abrupt	Slow but uneven	Variable, rapid, or slow but even
Duration	Hours to less than 1 month; seldom longer	Months to years	At least 6 weeks; can last several months to years

BOX 24-5 NURSING STORY

Pain and Delirium

Mr. D. R. was a 75-year-old man who underwent an elective right hip arthroplasty and was given patient-controlled anesthesia (PCA) for 48 hours. During that time, he did not use any additional dosages of morphine and was drowsy but alert and moving well. Approximately 10 hours after the PCA had been discontinued, he started to have episodes of confusion, in which he would not remember where he was. His wife, who was visiting him, came to the nurses' station, concerned about his confusion. The nurse measured his vital signs, which appeared to be normal with a slightly elevated pulse, but he had no fever. The nurse asked Mr. D. R. whether he was having pain; he responded, "Not really, just not feeling right." Throughout the night, he became increasingly confused. The nurse on the night shift applied her knowledge of postoperative delirium. Looking back at the medical record, she realized that Mr. D. R. had not had anything to control pain since the PCA had been discontinued. She also asked him whether he had pain, and he again said, "Not really." She used the Faces Pain Scale to assess Mr. D. R.'s pain, as recommended by the Hartford Foundation for Geriatric Nursing (Flaherty, 2007); his rating suggested that he was indeed having pain. The nurse gave him oral pain medication on a regular basis, and by morning, he was alert.

be hallucinations, occasional incoherent speech, disturbed sleep–wake cycle, and disorientation. The onset of delirium is typically sudden, and symptoms and severity fluctuate rapidly. The presence of delirium necessitates prompt assessment and intervention. The cognitive impairment secondary to delirium is usually reversed once the cause of delirium is identified and treatment is started, unless permanent brain injury has occurred. The story in Box 24-5 is a true one and exemplifies the importance of finding and treating the cause of delirium.

Treatment of delirium is focused on determining causative factors; however, prevention is also important. To prevent delirium and maintain patient functioning, you must address causative factors, which may be multidimensional. A strategy for delirium prevention and treatment that targets risk factors is implementation of a delirium protocol. An example of a protocol was described by Gillis and MacDonald (2006). In this protocol, you would assess the patient's cognition on a regular basis, using an assessment tool such as the Confusion Assessment Method (Waszynski, 2007). A medication profile and therapeutic environmental modification are also aspects of this protocol.

Dementia. Dementia is a syndrome consisting of a number of symptoms that include loss of memory, judgement, and reasoning and changes in mood, behaviour, and communication abilities. Deterioration of cognitive function leads to a decline in the ability to perform basic and instrumental ADLs. Unlike delirium, dementia is characterized by gradual, progressive, irreversible cerebral dysfunction. Because of the close resemblance of delirium to dementia, the presence of delirium must be ruled out whenever dementia is suspected. The Alzheimer Society of Canada (2008) classifies five major types of dementia: Alzheimer's disease, diffuse Lewy body disease, frontotemporal dementia, Creutzfeldt-Jacob dementia, and vascular dementia. The most common form of dementia is Alzheimer's disease. In Canada, approximately 34.5% of adults older than 85 years have dementia, in comparison with 2.4% of those aged 65 to 74 years (Alzheimer Society of Canada, 2008).

The cause of Alzheimer's disease is not known, and although several theories are being studied, none is definitive. Cholinesterase-inhibiting medications—memantine (Ebixa), donepezil (Aricept), rivastigmine (Exelon), and galantamine (Reminyl)—are currently prescribed to slow progression of symptoms. These medications prevent breakdown of the neurotransmitter acetylcholine by the enzyme cholinesterase. It is hypothesized that by increasing the amount of acetylcholine available to transmit impulses among neurons, cognition in some older adults with Alzheimer's disease will improve.

The characteristic progressive symptoms of Alzheimer's disease are loss of memory (amnesia), loss of the ability to recognize objects and people (agnosia), loss of the ability to perform familiar tasks (apraxia), and loss of language skills (aphasia). As Alzheimer's disease progresses, the affected adult becomes more dependent on caregivers for assistance with ADLs. Safety issues must be addressed as the disease progresses and the ability to judge risks diminishes.

Like Alzheimer's disease, diffuse Lewy body disease is progressive. The features of diffuse Lewy body disease include dementia, fluctuating cognition, visual or auditory hallucinations (or both), and the motor features of Parkinsonism.

Frontotemporal dementia has an insidious onset and progresses slowly. Early symptoms include poor hygiene, lack of social tact, hyperorality, and sexual disinhibition. Incontinence is also an early symptom in frontotemporal dementia, whereas it is a late symptom in the more common Alzheimer's disease. Repetitive behaviours (wandering, clapping, singing, picking up objects) are frequently observed. Safety and behaviour managements are major concerns for caregivers.

A sudden onset of memory loss, behaviour changes, or difficulties with speech and movement occur with

Creutzfeldt-Jakob disease (CJD). CJD is a rare, rapid, and fatal form of dementia caused by infectious agents called *prions*. Two types of CJD exist. *Classical CJD* (also called *sporadic CJD*) occurs at random. *Variant CJD* (vCJD) is a disease linked to eating beef products from cattle with bovine spongiform encephalopathy, also called “mad cow disease.” The infectious agent attacks the central nervous system, and the infection is fatal if illness develops. Both types of CJD typically cause memory loss and behavioural changes (Alzheimer Society of Canada, 2008).

The cause of vascular dementia is interruption of blood supply to areas of the brain by thromboembolism, hemorrhage, or ischemia. Symptoms of vascular dementia vary according to the areas of the brain affected. Progression of vascular dementia may be either stepwise, with repeated episodes of damage to the brain over time, or steadily progressive. Management of vascular dementia parallels the recommendations for cerebrovascular disease (i.e., reduction of risk factors by treatment of hypertension, hyperlipidemia, carotid disease, arrhythmias, diabetes mellitus, and polycythemia vera). Because the use of nicotine has been linked with vascular disease, older adults with vascular dementia should stop or reduce their use of tobacco products. If an older adult has a cardiac arrhythmia such as atrial fibrillation, anticoagulant therapy may be indicated to reduce the risk of thromboembolism.

In the nursing management of older adults with any form of dementia, you must consider the needs of the patient and the needs of the family. Those needs change because the progressive nature of dementia leads to increased cognitive deterioration. In addition to the patient’s physical needs, his or her safety needs and psychosocial needs must be considered. The patient’s family needs information and support. Nursing care objectives are the promotion of the use of remaining functional abilities and behavioural interventions to decrease the incidence of disruptive behaviours.

The Alzheimer Society of Canada (2008) has compiled suggestions for care of adults with dementia. The most challenging behaviours are those that include verbal and physical aggression. You should be calm and reassuring, look for an immediate cause, try distracting the patient, and, if safety is an issue, leave the situation and get assistance. Restraints cause physical harm and are not an efficacious alternative. Minimal restraint (policy of least restraint) for the shortest period of time should be used only as the last resort when safety is an issue.

Depression. Late-life depression may be experienced by 15% to 20% of older adults who live in the community (Canadian Coalition for Seniors’ Mental Health, 2008). Depression reduces happiness and well-being, contributes to physical and social limitations, complicates the treatment of concomitant medical conditions, and increases the risk of suicide. The manifestation of depression in older adults differs from that in younger adults. Older adults are more likely to talk about being “blue” or “down in the dumps” and may express feelings of diminished life satisfaction (Miller, in press). The mental health of seniors is a major issue facing older Canadians. It is estimated that 20% of Canadians older than 65 years are living with mental illness. Best practice guidelines for mental health treatment have been developed by the Canadian Coalition for Seniors’ Mental Health (2008).

Delirium and depression, both reversible disorders, are often mistaken for irreversible dementia in older adults because cerebral dysfunction and cognitive impairment occur with these conditions, as well as with dementia. Careful and

thorough assessment of older adults with cognitive impairment is essential to distinguish among delirium, dementia, and depression. As a beginning nurse, you may choose to consult with a clinical nurse specialist in gerontology. Accurate assessment is necessary to select appropriate nursing interventions.

Psychosocial Changes

The psychosocial changes that occur with aging involve changes in roles and relationships. Roles and relationships within the family change as parents become grandparents, as adult children become caregivers for aging parents, or as spouses become widows or widowers. Group membership roles and relationships change as older adults retire from work, move from a familiar neighbourhood, or stop attending social activities because of declining health status.

You should assess both the nature of the psychosocial changes facing an older adult and the adaptation of that adult to those changes. In the assessment, ask how the patient feels about himself or herself, about himself or herself in relation to others, and about himself or herself as aging. Areas to be addressed during the assessment include the family, intimate relationships, past and current occupation, finances, housing, social networks, activities, and spirituality. Specific topics related to these areas include retirement, housing and environment, social isolation, abuse, sexuality, and death.

Retirement. The great majority of Canadian older adults are retired; 6% of them are employed outside the home (Park, 2011). A large number (85%) of employed older adults work on a part-time basis (Figure 24-2). Many return to paid work after initial retirement; in 2002, 22% of Canadian retirees reported they had returned to paid work (Park, 2011). Older adults retired from employment outside the home are challenged to cope with the loss of that work role. Older adults who worked at home and the spouses of those who worked outside the home also face role changes as they retire.

Retirement is often mistakenly associated with passivity and seclusion. In actuality, it is a stage of life characterized by transitions and role changes. The psychosocial stresses of retirement may be related to role changes within the marital relationship or within the family and to loss of role. Problems may arise in relation to social isolation and finances. Retirement, which may be mandatory or voluntary, occurs at a

Figure 24-2 This older adult works part-time at a sporting goods store.

variety of ages. Regardless of the age at retirement, it is one of the major turning points in life.

Planning for retirement is an important, advisable task for middle-aged individuals. People who plan in advance for retirement generally have a smoother transition into that stage of life. Financial planning for retirement, although important, is only one aspect of retirement planning. Planning begins with consideration of the “style” of retirement desired and includes an inventory of interests, current skills, and general health. Meaningful retirement planning is critical because retirement can last for 30 years or more.

Retirement has an impact on other individuals besides the retired adult. Spouses, adult children, and grandchildren are all affected. When the spouse is still working, the retired adult faces time alone. For example, the working spouse may have new ideas about the amount of participation in housework expected of the retired adult. Friction may develop when the plans of the retired adult conflict with the work responsibilities of the working spouse. The working spouse's expectations of the retired adult must be clarified. For couples, adjustment to retirement is affected by the quality of communication with each other, their process of decision making about issues such as money or activities, their adherence to either traditional or shared role orientations, and their level of affection and intimacy (Ebersole et al., 2008). Adult children may expect the retired adult to become an automatic babysitter for grandchildren.

Loss of the work role has a major impact on some retired people. When so much of life has revolved around work and personal relationships at work, loss of the work role may be devastating. Personal identity may be rooted in the work role, and with retirement, a new identity must be constructed. The structure imposed on daily life by a work schedule is also lost, as are the social exchanges and interpersonal support that occur in the workplace. In the adjustment to retirement, older adults are challenged to develop a personally meaningful schedule and a supportive social network.

The most powerful factors that influence the retired adult's satisfaction with life are health status, the option to continue working, and sufficient income (Ebersole et al., 2008). Positive expectations also contribute to satisfaction in retirement. You can help an older adult and family prepare for retirement by discussing several key areas, including relationships with spouse and children, meaningful activities to replace the work role, adjusting or rebuilding social networks, issues related to the promotion and maintenance of income and health, and long-range planning, including wills and advance directives.

Social Isolation. Social isolation and loneliness are significant issues for older adults regardless of gender and geographic location (Cornwell & Waite, 2009). Social isolation is lack of contact with other people. Loneliness is dissatisfaction with the level of social contact. Isolation exists in two forms: a choice to not interact with others or a response to conditions that inhibit the ability or opportunity to interact with others (Ebersole et al., 2008). For example, geographic dispersion of families leads to decreased opportunities for interaction among family members. Regardless of whether isolation is a choice for older adults, they are vulnerable to its consequences.

Living alone and having multiple chronic illnesses are factors contributing to social isolation and loneliness (Cornwell & Waite, 2009). Some older adults see themselves as unattractive and rejected because of changes in their personal appearance as a result of normal aging or because of body

image changes caused by illness or surgery (Ebersole et al., 2008). Older adults who are confused or incontinent, who are unable to communicate, who are institutionalized, or who are poor or homeless may feel isolated.

You can assist lonely older adults to rebuild social networks and reverse patterns of isolation (Ebersole et al., 2008). Many communities have outreach programs designed to make contact with isolated older adults. Outreach programs, such as Meals on Wheels, may help meet nutritional needs; daily telephone calls by volunteers may help meet socialization needs; and outings may help meet needs for activities. Social service agencies in most communities welcome older adults as volunteers and provide them with the opportunity to serve and to be served. Other organizations within communities such as religious institutions, colleges, and libraries offer a variety of programs for older adults that increase the opportunity to meet people with similar activities, interests, and needs.

Abuse. Elder abuse is the mistreatment of an older adult by other people who are in a position of trust or power or who are responsible for the adult's care. Neglect is commonly associated with abuse. For example, elder abuse includes not performing an action (inaction) that a caretaker has a duty to perform, such as not providing medications to an older adult who needs them (Canadian Network for the Prevention of Elder Abuse, 2008). Types of abuse are as follows:

- Physical abuse: use of physical force that may result in bodily injury, physical pain, or impairment
- Sexual abuse: nonconsensual sexual contact of any kind, which includes sexual contact with any adult incapable of giving consent
- Psychological or emotional abuse: infliction of anguish, emotional pain, or distress through verbal or nonverbal acts
- Material abuse (financial abuse): illegal or improper exploitation of an older adult's funds, property, or assets
- Neglect: the intentional or unintentional harmful behaviour on the part of an informal or formal caregiver in whom the older adult has placed his or her trust
- Self-neglect: behaviour by an older adult that threatens their health and safety such as not eating

In most provinces in Canada, elder abuse must be reported. As a nurse, you play an important role in assessment, recognition, and reporting of elder abuse, as well as its prevention, through education and resources for families (Box 24-6).

Sexuality. Sexuality is increasingly recognized as an important factor in the lives of older adults. All older adults, whether healthy or frail, need to express sexual feelings. Sexuality involves love, warmth, sharing, and touching, not just the act of intercourse. Sexuality is linked with identity and validates the belief that people can give of themselves to others and have the gift appreciated.

Maintaining sexual health requires integration of somatic, emotional, intellectual, and social aspects of the sexual being. To help an older adult achieve or maintain sexual health, you should understand the physical changes in sexual response (see Chapter 26). You should provide privacy for any discussion of sexuality and should maintain a nonjudgemental attitude. Open-ended questions inviting the patient to explain sexual activities or concerns may elicit more information than do closed-ended questions about specific activities or symptoms. Older adults may appreciate information about the typical age-related changes in sexuality. Information about the prevention of sexually transmitted infections should be included when appropriate. The libido does not decrease in

► BOX 24-6

Elder Abuse: Signs and Action Required**Signs**

Physical signs of abuse
 Isolation from others
 Withdrawal
 Confusion, depression, or anxiety
 Changes in hygiene
 Seeming fearful around certain people
 Fear or worry when talking about money
 Feeling of the victim that he or she is to blame
 Verbalized threats against the victim

Action Required

Assess the presence of physical danger and if imminent danger report it to police
 Contact Family Violence Hot Line
 Support the victim's decision to leave the situation or to stay in it
 Develop a workable safety plan
 Provide specific information about places of safety

Adapted from Ebersole, P., Hess, P., Touhy, T., Jett, K., & Luggen, A. (2008). *Toward healthy aging: Human needs and nursing response* (7th ed.). St Louis, MO: Mosby.

older adults, although frequency of sexual activity may decline. An older woman who does not understand physical changes affecting sexual activity may be concerned that her sex life is nearly over. The older man may feel the same when he discovers a change in the firmness of his erection, a decreased need for ejaculation with each orgasm, or a longer recovery period between episodes of intercourse.

In addition to the physical changes that affect sexual functioning, many older adults use prescription medications that depress libido, such as antihypertensives, antidepressants, sedatives, and hypnotics. Some drugs increase libido in older adults. For example, phenothiazines increase sexual desire in women, and levodopa has a similar effect in men.

While considering an older adult's need for sexual expression, you must not ignore the important need to touch and be touched. Touch is an overt expression with many meanings and is an important part of sexuality in some cultures. Touch can complement traditional sexual methods or serve as an alternative sexual expression when physical intercourse is not desired or possible, and thus it can serve as an important method of achieving intimacy (Atkinson, 2006). Before using touch, you should respect the fact that it may not be appropriate for some older adults because of culturally associated meanings. Experience in caring for older adults, in combination with the ability to establish therapeutic connection, enables you to learn how to explore patients' sexual concerns. Knowing an older adult's sexual needs allows you to incorporate this information into the nursing care plan.

The sexual preferences of older adults are as diverse as those of younger persons. Not all older adults are heterosexual. Little information regarding older homosexual adults and their health care needs is available. To be effective caregivers for older homosexual patients, you need to be aware of your own beliefs about sexuality and the potential impact of those beliefs on your ability to provide care.

Improving communication and creating open and supportive environments of care are necessary to promote successful, healthy sexual expression.

You may find that you are called on to advise older adults and help other health care providers understand the sexual needs of older adults. You may feel uncomfortable counselling older adults about sexual health and need not feel obligated to do so. But you should be prepared to refer older adults to appropriate professional counsellors.

Housing and Environment. Most Canadians want to stay in their communities as long as possible (Special Senate Committee on Aging, 2009). However, housing choices are strongly determined by an older adult's ability to live independently. Changes in social roles, family responsibilities, health status, retirement, and income influence this ability. For example, physical impairments may necessitate relocation to a smaller, single-level home. Because of health problems, an older adult may need to live with relatives or friends or move to an assisted-living or long-term care facility. A change in living arrangements may require an extended period of adjustment during which assistance and support from health care providers, friends, and family members are needed.

Some older adults choose to live with family members. Others prefer their own homes or apartments near their families. Leisure or retirement communities provide older people with living and social opportunities in a one-generation setting. Federally subsidized housing, where available, offers apartments with communal, social, and, in some cases, food service arrangements. However, although they may change residence, the majority of Canadian older adults report that they enjoy good housing (National Advisory Committee on Aging [NACA], 2006). There are Canadians, however, who because of poverty are unable to find adequate housing (Special Senate Committee on Aging, 2009). The Special Senate Committee on Aging (2009) has recommended that elimination of poverty for older adults be a goal of the Canadian government. When assisting older adults with housing needs, you should assess activity level, financial status, availability of access to public transportation and community activities, environmental hazards, and support systems. Housing choices should also account for anticipated future needs of the patients. A housing unit with only one floor and without exterior steps may be a prudent choice for an older adult with severe arthritis who has already had some lower extremity joint replacement surgeries and anticipates the need for future surgeries.

Housing and environment have a major impact on the health of older adults. The environment can support or hinder physical and social functioning, can enhance or drain energy, and can complement or tax existing physical changes such as vision and hearing. For example, older adults can most easily see the colours red, orange, and yellow; in contrast, they have difficulty distinguishing between green and blue and among pastel shades. To help older adults in health care settings find their rooms, pictures or other decorations near their doors can be used as landmarks. To improve perception of the boundaries of halls and rooms, door frames and baseboards should be painted in a colour that contrasts with the colour of the wall. Glare from highly polished floors, metallic fixtures, and windows are poorly tolerated.

Furniture should be comfortable and designed for the musculoskeletal changes of older adults. Older adults should examine furniture carefully for size, comfort, and function before purchasing it. Furniture should be easy to get into and out of and should provide back support. Dining room chairs should be tested for comfort during meals and height in relation to the table. Older adults may prefer transferring out of a

wheelchair to another chair for meals because some styles of wheelchairs prevent sitting close enough to the table to eat comfortably. Raising the table to clear the wheelchair arms may bring the table closer to the adult but make it too high for comfortable use. To make getting out of bed easier and safer, the height of the bed should allow the adult's feet to be flat on the floor when the adult is sitting on the side of the bed.

The goal of nursing assessment of the environment is the promotion of independence and functional ability. Assessment of safety, a major component of an older adult's environment, includes determining risks within the environment and the adult's ability to recognize and respond to the risks (see Chapter 36). Risks include factors leading to injury within the home (such as water heaters set at excessively hot temperatures or throw rugs that could cause a fall) and factors outside of the home (such as deteriorating sidewalks and steps or a high incidence of street crime).

Death. Part of the life history of an older adult is the experience of the death of family members and friends (see Chapter 28). This experience includes the loss of the older generations of their families and sometimes the loss of a child or grandchild. As adults age, friends gradually die. The majority of older adults are faced with the death of a spouse. In 2001, 28% of all older women were widows, and 12.7% of older men were widowers (Statistics Canada, 2008). Some older adults must also cope with the death of children and grandchildren. All experience the deaths of friends. These deaths represent both losses and reminders of personal mortality. You should not, however, assume that older adults are comfortable with the idea of death. Coming to terms with death is often difficult. As a nurse, you will play a key role in assisting older adults through the grieving process.

Older people have a wide variety of attitudes and beliefs about death. To support a patient at the end of life, you can use the dignity-conserving model of care (Chochinov, 2007). In this model, you use your attitudes, behaviours, compassion, and dialogue acknowledging the individual's attitudes and beliefs about death to ensure his or her dignity at the end of life. Another model of care that you can use is a Living with Hope program (Duggleby et al., 2007) to foster his or her hope and improve quality of life. Such strategies to improve end-of-life care can be easily incorporated into everyday nursing practice. You will often be the adult to whom the patient and family members or friends turn for assistance in coping with death and loss. It is critical that you understand the grieving process, have excellent communication skills, understand the legal issues, are familiar with community resources, and are aware of your own feelings, limitations, and strengths as they relate to the care of patients confronting death.

Addressing the Health Concerns of Older Adults

The two most common causes of death in Canadian older adults are cancer and heart disease. Other frequently reported causes of death are respiratory diseases, stroke, accidents or falls, diabetes, kidney disease, and liver disease (Statistics Canada, 2008). For all these causes of death, preventive measures exist that could potentially reduce the frequency of these conditions and delay disability, death, or both.

You may participate in activities such as health screenings and health fairs, in which you can identify older adults at risk and advise them about disease prevention and health promotion measures. Many communities offer wellness programs

* BOX 24-7

FOCUS ON PRIMARY HEALTH CARE

Older Adult Wellness Programs

An important nursing intervention occurs when nurses focus on self-care abilities and practices that foster health during the aging process. Factors that have been reported to affect older adults' willingness to engage in health promotion activities include socioeconomic factors, beliefs and attitudes, encouragement by a health care provider, availability of access to resources, age, number of chronic illnesses, and mental and physical health (Resnick et al., 2008). In general, older adults seem to be less interested in engaging in health promotion activities for the purpose of lengthening their lives, but they may have greater interest in these activities if they improve quality of life (Resnick et al., 2008).

To help older adults maintain function and improve quality of life, the Saskatoon Health Region, in conjunction with several other community agencies, established an Older Adult Wellness Program. The program goals are as follows:

1. Encourage older adults to adopt lifestyle choices and practices that preserve their health.
2. Promote the concept of mutual aid and social support among older adults in the community (capacity building).
3. Alter or adapt social, economic, or physical surroundings to preserve and enhance the health of older adults.

The program is housed in a primary health centre. As part of this program, the nurses provide educational programs about promoting older adults' health to seniors living in the community, to health care providers, and to students enrolled in health care programs. The nurses collaborate with other community and regional health authority agencies to provide information and programs to increase physical activity, identify fall risks, and promote the prevention of falls. Preventive services such as health screening and immunizations are also offered to older adults. A directory of services and social activities for older adults has been published by the Saskatoon Council on Aging with assistance from Older Adult Wellness and the College of Kinesiology, University of Saskatchewan. This directory is used by older adults and the nurses to access services for program participants.

(Box 24-7) in which older adults can access information about health promotion and disease prevention. In acute care and long-term care settings, you must also assess the health status of older adults, intervene in acute situations, and, with the patients, plan strategies to reduce risk and manage chronic conditions. Each contact with an older adult, regardless of setting, offers opportunities to teach and counsel. To be most effective, use an individualized approach to health promotion activities with each patient (Resnick et al., 2008).

Nursing interventions for older adults are directed toward improving or maintaining their health needs and concerns. Although various interventions cross all three levels of care—health promotion, acute care, and restorative care—approaches to each level are unique. When you plan interventions, it is important to incorporate a patient's routines or rituals when possible because patients feel more secure when routines are continued. In general, the interventions are aimed at promoting independence and supporting self-care abilities.

Health Promotion and Maintenance: Physiological Health Concerns

Older adults, like adults of any age, vary in their desire to participate in health promotion activities; therefore, you should use an individualized approach, taking into account the adult's beliefs about the importance of staying healthy and fit and remaining independent. Researchers have not fully identified the factors that lead to good health in advanced age, but four factors seem to be important: genetics, chance, good health habits, and preventive measures. You cannot alter an older adult's genetic heritage or chance, but you can promote health habits by establishing health maintenance programs, and you can recommend preventive measures. Health maintenance programs have been found to have a positive impact on the physical, mental, and social health of older adults. Community centres, houses of worship, schools, shopping malls, libraries, and hospital lobbies can be used as settings to conduct screening tests and present information on health topics. Using creative approaches, you can include health promotion activities for older adults in all health care settings.

Approximately 80% of older adults living at home have at least one chronic health condition. The most common conditions are arthritis, high blood pressure, back problems, chronic heart problems, cataracts, and diabetes (Statistics Canada, 2008). The effect of chronic conditions on the lives of older adults varies widely, but, in general, chronic conditions diminish well-being and threaten independence. Nursing interventions are often directed at the management of these conditions, but interventions can also focus on prevention. You can recommend the following general preventive measures:

- Regular exercise
- Weight reduction if the older person is overweight
- Management of hypertension
- Smoking cessation
- Immunization for influenza, pneumococcal pneumonia, and tetanus

A Canadian study reported that as the numbers of adults receiving an influenza vaccination increased, hospitalizations decreased (Chen et al., 2010). Annual immunization against influenza is strongly recommended for all older adults, especially residents of long-term care facilities and persons of any age with chronic cardiovascular, pulmonary, and metabolic disorders. Vaccination against pneumococcal pneumonia is recommended for all adults older than 65 years. Influenza vaccine is needed every year, whereas pneumococcal pneumonia vaccine is given only once (although some authorities recommend revaccination six to eight years after the initial vaccination). For tetanus immunization, booster injections every ten years are recommended for adults who have received the primary series for tetanus immunization. However, not all older adults are up to date with their booster injections, and some have never received the primary series of injections. You should ask an older adult about the current status of all three types of immunizations, provide information about the immunizations, and make arrangements for the older person to receive the immunizations as needed. You should also refer older adults for screening for the early detection of cancer and depression.

Most older adults are interested in their health and are capable of taking charge of their lives. They want to remain independent and to prevent disability (see Figure 24-2). Initial screenings establish baseline data that can be used to determine wellness, identify health needs, and design health

maintenance programs. After initial screening sessions, you can share information on nutrition, exercise, medications, and safety precautions with older adults. You may also provide information about specific conditions, such as hypertension or arthritis, or about self-care procedures, such as foot and skin care. By providing information about health promotion and self-care, you can significantly improve the health and well-being of older adults.

Cancer. Malignant neoplasms are the most common cause of death among older adults (Statistics Canada, 2008). You may participate in programs to educate older adults about early detection, treatment, and risk factors. Examples include smoking cessation programs, teaching breast self-examination (see Chapter 4), and encouraging all older adults to have annual screening for fecal occult blood. It is also important to educate older adults about the signs of cancer and encourage prompt reporting of nonhealing skin lesions, unexpected bleeding, change in bowel habits, and unexplained weight loss. Detection is complicated when cancer symptoms are mistakenly identified by patients and health care providers as part of the normal aging process, and you must carefully distinguish between normal aging and pathological conditions.

Heart Disease. Heart disease is the second leading cause of death in older adults. Common cardiovascular disorders are hypertension and coronary artery disease. Hypertension is diagnosed when repeated diastolic blood pressure measurements are 90 mm Hg or greater and systolic measurements are 140 mm Hg or greater. Although over 45% of Canadians have elevated diastolic or systolic pressures or both (NACA, 2006), the fact that hypertension is common does not mean it is normal or harmless. Systolic pressures higher than 160 mm Hg are associated with increased risk of stroke, cardiovascular mortality, and overall mortality. In coronary artery disease, partial or complete blockage of one or more coronary arteries leads to myocardial ischemia and myocardial infarction. Risk factors for both hypertension and coronary artery disease include smoking, obesity, lack of exercise, and stress. Additional risk factors for coronary artery disease include hypertension, hyperlipidemia, and diabetes mellitus. Nursing interventions for hypertension and coronary artery disease address weight reduction, exercise, dietary changes to limit salt and fat, stress management, and smoking cessation. Patient education includes information about medications, blood pressure monitoring, nutrition, stress reduction techniques, and the symptoms that indicate the need for emergency care.

Smoking. Cigarette smoking has been recognized as the major preventable cause of death and disease in Canada (Canadian Council on Social Development for the Division of Aging and Seniors, Public Health Agency of Canada, 2004). Smoking cessation is a health promotion strategy as much for older adults as for younger adults. Older smokers can benefit from smoking cessation (Tait et al., 2007). In addition to reducing risk, smoking cessation may help stabilize existing conditions such as chronic obstructive pulmonary disease. Smoking cessation may even contribute to the extension of life or of independent functioning. There are many types of smoking cessation programs available to older adults, and you should provide information to the older adult about those programs.

Alcohol Abuse. It is estimated that up to 12% of older adults consume 14 or more drinks a week (Statistics Canada, 2008). Studies of alcohol abuse in older adults have revealed two patterns: a lifelong pattern of frequent heavy drinking and a late-onset pattern in which heavy drinking begins late in life.

Frequently cited causes of excessive alcohol use are depression, loneliness, and lack of social support.

Abuse of alcohol may be underidentified in older adults (Ebersole et al., 2008). Signs of alcohol abuse are subtle, and the assessment may be complicated by coexisting dementia or depression. Alcohol abuse should be suspected when the patient has a history of repeated falls and accidents, exhibits a change in behaviour or personality, is socially isolated, has recurring episodes of memory loss and confusion, has a history of skipping meals or medications, and has difficulty managing household tasks and finances. When abuse of alcohol is suspected, treatment includes age-specific approaches in which you acknowledge the stresses experienced by the patient and encourage involvement in activities that match the patient's interests and boost feelings of self-worth. The identification and treatment of coexisting depression is also important.

Nutrition. Lifelong eating habits and situational factors influence how older adults meet their needs for good nutrition. Lifelong eating habits based in tradition, ethnicity, and religion influence choices of what foods are eaten and how those foods are prepared. Situational factors affecting nutrition include availability of access to food stores, finances, the physical and cognitive capability for food preparation, and a place to store food and prepare meals. Undernutrition can be a significant deterrent to healthy aging (Furman, 2006).

Nutritional needs of older adults are affected by levels of activity and by clinical conditions. Level of activity has implications for the total amount of calories: more sedentary older adults usually need fewer calories than more active older adults. However, caloric requirements are not determined solely by activity. Additional calories may be required in clinical situations such as recovery from surgery, whereas calories may be restricted when the patient is diabetic or overweight. Beyond caloric requirements, therapeutic diets may restrict fat, sodium, or simple sugars or may increase fibre or foods with high levels of calcium, iron, vitamin A, or vitamin C.

Good nutrition for older adults includes appropriate caloric intake and limited intake of fat, salt, refined sugars, and alcohol. Although the nutritional guidelines displayed in Canada's Food Guide (Health Canada, 2007) are the basic recommendations for nutrition in older adults (see Chapter 42), some older adults do not follow these guidelines. Protein intake may be lower than recommended if patients have reduced financial resources or limited access to grocery stores. Difficulty chewing meat may also limit protein intake. Fat intake may be higher than recommended because fast-food restaurant meals may be substituted for meals prepared at home or because methods of cooking may feature fried foods and sauces made with butter and cream. Extra salt and sugar may be used in cooking or at the table to compensate for a diminished sense of taste. Vitamin intake may be reduced if the adult has difficulty shopping for fresh fruits and vegetables. As a nurse, you should assess the nutritional status of older adults in all settings and identify interventions to improve their nutritional status (Furman, 2006).

Older adults with dementia have special nutritional needs. As memory and functional skills decline, they lose the ability to remember when to eat, how to prepare food, and, eventually, how to feed themselves. At the same time, caloric needs may increase because of the energy expended in pacing and wandering activities. You and other caregivers of older adults with dementia should routinely monitor weight and food intake, serve food that is easy to eat, provide assistance with

eating, and offer food supplements as needed to maintain weight. Mealtime interventions for older adults with dementia provide opportunities for socialization and practice with functional skills.

Dental Problems. Dental problems are common in older adults and include conditions involving natural teeth and dentures. Dental caries, gingivitis, broken or missing teeth, and ill-fitting or missing dentures may affect nutritional adequacy, cause pain, and lead to infection. You can help prevent dental and gum disease through education about routine dental care (see Chapter 37). You can also help older adults find dental services that offer reduced rates and that are accessible to patients with impaired mobility.

Exercise. Older adults should be encouraged to maintain physical exercise and activity. The primary benefits of exercise include maintaining and strengthening functional ability and promoting a sense of enhanced well-being. Mobility is important to older adults for maintaining their physical and psychological health (Webber et al., 2010). An exercise such as walking builds endurance, increases muscle tone, improves joint flexibility, strengthens bones, reduces stress, and contributes to weight loss. Other benefits of an exercise program include improvement of cardiovascular function, improved plasma lipoprotein profiles, increased metabolic rate, increased gastrointestinal transit time, and improved quality of sleep. Frail older adults who exercise may experience improvements in mobility, gait, and balance, as well as less difficulty getting up from a chair or climbing stairs. Exercise also substantially delays the onset of functional impairment and loss of independence. As well, over half of nursing home residents with middle-stage dementia walking difficulties can be improved (Slaughter et al., 2011). You can help adults with dementia continue to be able to walk and exercise by creating supportive environments and making sure they get appropriate medications.

An exercise program should meet physical needs while allowing for physical impairments, and you should encourage the patient to persevere with the program. Willingness to participate in and persevere with an exercise program is influenced by general beliefs about exercise, specific benefits from exercise, past experiences with exercise, personal goals, personality, and any unpleasant sensations associated with exercise. Walking is the preferred exercise of many older adults (Figure 24-3). Walking and other low-impact exercises such as riding an exercise (stationary) bicycle or exercises in a swimming pool protect the musculoskeletal system and joints. Other exercises can be incorporated into an older adult's ADLs. For example, the adult can perform arm and leg circles while watching television. However, before beginning an exercise program, the older adult should have a physical examination. Exercise programs for sedentary older adults who have not been exercising regularly should begin conservatively and progress slowly. Safety considerations include wearing appropriate shoes and clothing, drinking water before and after exercising, avoiding outdoor exercise when the weather is very warm or very cold, and exercising with one or more partners. You should instruct the older adult to stop exercising and seek help if he or she experiences tightness or pain in the chest, shortness of breath, dizziness or lightheadedness, or palpitations during exercise.

Arthritis. Arthritis is common in older adults, especially women. The degree to which the mobility of older adults is impaired depends on the extent of disease and which joints are affected. Changes in joint range of motion and stability,

Figure 24-3 This couple enjoys walking together.

combined with the amount of pain experienced, affect quality of life. Arthritis has no cure, but pharmacological agents can decrease pain and swelling and therefore increase joint motion. Nursing interventions are aimed at promoting comfort, functional ability, and safety. Education on self-care techniques, joint protection, and exercises for flexibility and strength is also important.

Falls. Falls are a safety concern and one of the most common causes of functional dependence in seniors. Falls may lead to fear of additional falls, withdrawal from usual activities, and loss of independence (see Chapter 36). Hospitalization and placement in a long-term care facility may be required. Falls account for 87% of unintentional injuries that result in hospitalization for adults aged 71 years and older and for 75% of the deaths from injury in this age group (NACA, 2006). A fracture is sustained in 5% of falls in this age group. Falls are more frequent and have more serious consequences among adults older than 85 years.

Falls are caused by a combination of individual and environmental factors (RNAO, 2005a). Individual factors include impaired vision; cardiovascular conditions, such as postural hypotension or syncope; conditions affecting mobility, such as arthritis, muscle weakness, and foot problems; conditions affecting balance; alterations in bladder function, such as frequency or incontinence; cognitive impairment; and adverse medication reactions. Environmental factors include, but are not limited to, poor lighting, slippery or wet floors, stairs or sidewalks in poor repair, shoes in poor repair or with slippery soles, and household items that could be tripped over, such as throw rugs, foot stools, and electric extension cords. Multifactor falls-prevention programs such as “Stand-Up” have been found to significantly reduce falls in community-dwelling older people (Filiatrault et al., 2007). This program includes exercises to increase balance and strength, adoption of active lifestyles and safe behaviours, and actions to reduce hazards

in the home environment. You can encourage older adults to perform exercises aimed at increasing leg strength and balance, which also reduce the risk of falls. Simple interventions in the home, such as rearranging furniture to provide a clear pathway to the bathroom and providing a night light in the bathroom, can reduce falls related to nighttime trips to the toilet. Removing throw rugs and other items on the floor helps reduce slipping and tripping. You can also instruct older adults in the safe use of assistive devices such as canes, walkers, and wheelchairs. Older adults taking medications that may have adverse effects, such as postural hypotension, dizziness, or sedation, can be instructed to be aware of these potential effects and to take precautions such as changing position slowly or holding on to sturdy furniture if they are unsteady. Other health conditions such as ear infections can also contribute to falls.

Sensory Impairments. Most older adults have changes in vision, hearing, taste, and smell as a result of normal aging. Chapter 47 describes in detail the nursing interventions used to maintain and improve sensory function.

Pain. At least 50% of older adults suffer pain at any one time, and pain is undertreated (Hadjistavropoulos & Fine, 2006). Causes of pain in older adults include acute and chronic conditions (e.g., trauma, infection, neuropathies). Consequences of persistent pain include depression, sleep difficulties, changes in gait and mobility, and decreased socialization. Older adults are most at risk of having their pain inadequately assessed and treated (McAuliffe et al., 2009). Many factors influence the management of pain, including cultural influences on the meaning and expression of pain in older adults, fears related to the use of analgesic medications, and the problem of pain assessment with cognitively impaired older adults.

The Hartford Institute for Geriatric Nursing has several recommendations for assessing pain in older adults and have developed a pain management standard of practice protocol (Horgas & Yoon, 2011). You as a nurse should utilize these assessment tools and a variety of pharmacological and non-pharmacological interventions to manage older adults’ pain (Morone & Greco, 2007).

In caring for older adults you must advocate for appropriate and effective pain management and for the use of standardized pain tools in assessing pain (see Chapter 41). The goal of nursing management of pain in older adults is to maximize function and improve quality of life.

Medication Use. Older adults take more prescription and over-the-counter drugs than do people of any other age group. Older adults account for 12% of the population but use as much as 40% of prescription medications (NACA, 2006). In 2003, 92% of Canadian older adults reported using medications in the previous month (NACA, 2006). The medications most commonly used are cardiovascular drugs, antihypertensives, analgesics, sedatives, tranquilizers, laxatives, and antacids. **Polypharmacy** (the concurrent use of many medications) increases the risk for adverse reactions. Although polypharmacy may reflect inappropriate prescribing, the concurrent use of multiple medications may be necessary if the older adult has multiple acute and chronic conditions. However, a periodic and thorough review of all medications being used is important in helping older adults use the fewest necessary medications. Your role with an older adult undergoing drug therapy is to ensure the greatest therapeutic benefit with the least amount of harm. A good resource to help you is *Medication Matters* (Division of Aging and Seniors, Public Health Agency of Canada, 2008).

Older adults are at risk for adverse reactions because of age-related changes in the absorption, distribution, metabolism, and excretion of drugs (see Chapter 33). Medications may interact with one another; one drug may augment or negate the effect of another. Medications may also cause confusion; affect balance and mobility; cause dizziness, nausea, and vomiting; or lead to constipation, urinary frequency, or incontinence. Because of these effects, some older adults are unwilling to take medications, and others do not adhere to the prescribed dosing schedule.

Managing medications is a very important component of maintaining and promoting good health in old age. For some older adults taking large numbers of medications, safely managing medications can be a complex activity that can easily become overwhelming. You can provide valuable assistance to these older adults as they carry out this important self-care activity.

You should work collaboratively with an older adult to ensure safe and appropriate use of prescribed and over-the-counter medications. The older adult should be taught the names of all drugs being taken, when and how to take them, and the desirable and undesirable effects of the drugs. You should also teach how to avoid adverse effects and interactions of drugs and how to establish and follow an appropriate self-administration pattern. To reduce the risk for an adverse medication reaction, you should review the medications at each visit; examine for potential interactions with food or other drugs; simplify and individualize the drug regimen; take every opportunity to inform the older adult and family about all aspects of medication use; and encourage them to question the physician, advanced practice nurse, pharmacist, or all three about all prescribed and over-the-counter drugs.

When drugs are used in the management of confusion, special care is necessary. The sedatives and tranquilizers sometimes prescribed for acutely confused older adults may themselves cause or exacerbate confusion. These drugs should be carefully administered; age-related changes in body systems can affect the pharmacokinetic activity. When confusion has a physiological cause (such as an infection), the cause, rather than the confused behaviour, should be specifically treated. When confusion varies by time of day or is related to environmental factors, you can use creative, nonpharmacological measures such as changing the environment to include things that are familiar to the patient, providing adequate light, encouraging use of assistive devices (glasses, hearing aids), or even encouraging the older adult to make telephone calls to friends or family members to hear reassuring voices.

Health Promotion and Maintenance: Psychosocial Health Concerns

Interventions supporting psychosocial health of older adults resemble those for other age groups. However, some interventions are more crucial for older adults experiencing social isolation, cognitive impairment, or stresses related to retirement, relocation, or approaching death. These interventions include therapeutic communication, touch, cognitive stimulation, reminiscence, and measures to improve body image.

Therapeutic Communication. With therapeutic communication, you perceive and respect the older person's uniqueness and meet his or her expectations. Older adults expect you to be attentive, caring, and knowledgeable. Being attentive means providing care in a timely manner and meeting the older adult's expressed or unexpressed needs. As a caring nurse, you convey concern, kindness, and compassion. To

show that you are knowledgeable, you demonstrate procedural competence and are adept at recognizing needs and relaying information. Older adults also expect you to respect their individuality. When you meet expectations and communicate effectively, they accept you as someone who has a genuine concern for their welfare. However, you cannot simply enter an older adult's environment and immediately establish a therapeutic relationship; you must first be knowledgeable and skilled in communication techniques (see Chapter 17).

Touch. Throughout life, touch tells people about their environment and the people around them. Gentle touch conveys affection and friendliness. A firm hand clasp may convey security. Touch is a therapeutic tool that you can use to help comfort older adults. Hawranick et al. (2008) found that agitation levels of older adults with dementia were significantly lower when they received a touch intervention (Box 24-8). Touch can provide sensory stimulation, induce relaxation, provide physical and emotional comfort, orient the adult to reality, convey warmth, and communicate interest. It is a powerful physical expression of a relationship.

Older adults may be deprived of touching when separated from family or friends. An older adult who is isolated, dependent, or ill; fears death; or lacks self-esteem has a greater need for touch. You may recognize touch deprivation by behaviours as simple as an older person reaching for your hand or standing close to you. When you use touch, you must be aware of

* BOX 24-8

EVIDENCE-INFORMED PRACTICE GUIDELINE

Therapeutic Touch and Agitation in Individuals with Alzheimer's Disease

Evidence Summary

Very few strategies to alleviate or treat disruptive behaviour are effective in people with Alzheimer's disease. The purpose of a 2008 study by Hawranick et al. was to compare the effectiveness of therapeutic touch (identifying and correcting energy imbalances by passing hands several inches above the patient's body), simulated therapeutic touch (moving hands over the patient's body without energy transfer), and usual care on the disruptive behaviour of 51 subjects with Alzheimer's disease who were receiving long-term care. Disruptive behaviour was classified into three categories: physical aggression, physical nonaggression, and verbal agitation. Physical nonaggressive behaviours decreased significantly in subjects who received therapeutic touch, in comparison with those who received the simulated version and usual care. All categories of disruptive behaviours decreased over time in both the subjects receiving therapeutic touch and those receiving simulated therapeutic touch.

Application to Nursing Practice

- Therapeutic touch and simulated therapeutic touch are effective in reducing disruptive behaviours in patients with Alzheimer's disease.
- These touch techniques can be taught to family members, staff, and volunteers.
- These techniques can help calm the agitated adult and enhance communication during visits.

Based on Hawranick, P., Johnston, P., & Deatrich, J. (2008). Therapeutic touch and agitation in individuals with Alzheimer's disease. *Western Journal of Nursing Research*, 30(4), 417-434.

cultural variations and individual preferences (see Chapter 9). Touch should convey respect and sensitivity; it should not be used in a condescending way, such as patting an older adult on the head.

Cognitive Simulation. Cognitive stimulation, in which adults engage in cognitive activities such as games, appears to show promise in improving cognitive function in adults with moderate to severe dementia (Knowles, 2010). It is considered more effective and less confrontational than reality orientation techniques, although it does include some aspects of reality orientation. An example of cognitive stimulation is the use of a reality orientation board with personal and orientation information combined with sessions of cognitive exercises involving memory, problem solving, and conversation (Knowles, 2010). Some older adults may benefit more from cognitive stimulation than do others, but this still remains unknown. Until more information is available, you should be sensitive to individuals' responses. You should always be respectful, patient, and calm, and in communicating, you should answer questions simply, honestly, and with sensitivity.

Reminiscence. Reminiscence is recalling the past. Many older adults find enjoyment in sharing past experiences. In reminiscence as therapy, the recollection of the past is used to find meaning and understanding of the present and to resolve current conflicts. Remembering positive resolutions to problems reminds older adults of previous coping strategies used successfully. Reminiscing is also a way to express personal identity. Reflection on past achievements supports self-esteem. For some older adults, the process of remembering past events uncovers new meanings for those events and fosters hope (Duggleby & Wright, 2005). Short term life-review interviews have been found to increase hope and spiritual well-being in terminally ill patients (Ando et al., 2010).

During the assessment process, you may use reminiscence to assess self-esteem, cognitive function, emotional stability, unresolved conflicts, coping ability, and expectations for the future. Reminiscence also occurs during direct care activities. Taking time to ask the patient questions about his or her experiences and listening attentively conveys to an older adult your attitude of respect and concern.

Although reminiscence is often useful in a one-on-one situation with older adults, reminiscence can also be useful in group therapy for cognitively impaired or depressed older adults. You can organize the group and select strategies to start a conversation (e.g., ask the group to discuss families or childhood memories). The group's size, structure, process, goals, and activities are adapted to meet its members' needs.

Body-Image Interventions. The way that older adults present themselves influences body image and feelings of isolation. Some physical characteristics of older adulthood, such as distinguished-looking grey hair, may be socially desirable. Other features, such as a lined face that displays character or wrinkled hands that convey a lifetime of hard work, may also be impressive. Consequences of illness and aging that threaten the older adult's body image include invasive diagnostic procedures, pain, surgery, loss of sensation in a body part, skin changes, loss of scalp hair, and incontinence. Body image is also affected by the use of devices such as dentures, hearing aids, artificial limbs, indwelling catheters, ostomy devices, and enteral feeding tubes.

The importance to the older adult of presenting a socially acceptable image must be considered. When older adults have acute or chronic illnesses, the related physical dependence

makes it difficult for them to maintain body image. You can influence the older adult's appearance by assisting with grooming and hygiene, such as combing hair, cleaning dentures, shaving, or changing clothing. You should also be sensitive to odours in the environment. Odours may be created by urine and some illnesses. By controlling odours, you may encourage visitors to stay longer or visit more often.

Older Adults and the Acute Care Setting

Older adults in the acute care setting need special attention to help them adjust to the acute care environment and to meet their basic needs for comfort, safety, nutrition, hydration, and skin integrity. The acute care setting poses increased risk for adverse events such as delirium, dehydration, malnutrition, nosocomial infections, urinary incontinence, and falls.

The risk for delirium is increased when hospitalized older adults experience immobilization, infection, dehydration, pain, and hypoxia. Multiple medications and multiple medical diagnoses are also risk factors. Nonmedical causes include placement in unfamiliar surroundings, separation from supportive family members, and stress. Impaired vision or hearing contributes to confusion and interferes with nurses' attempts to reorient the patient. When prevention of delirium fails, the basis of nursing management is identification and treatment of the cause of delirium. Supportive interventions include encouraging family visits, providing memory cues (e.g., clocks, calendars, name tags), and compensating for sensory deficits. Reality orientation techniques may be useful.

Older adults are at greater risk for dehydration and malnutrition during hospitalization because of standard procedures such as limiting food and fluids in preparation for diagnostic tests. The risk for dehydration and malnutrition is also increased when older adults are unable to reach beverages or to feed themselves while in bed or connected to medical equipment. Interventions include getting the patient out of bed, providing beverages and snacks frequently, and including favourite foods and beverages in the diet plan.

The risk for nosocomial infections in older adults is increased by age-related reductions in immune system response. Of all health care agency-acquired infections, 65% occur in hospitalized patients older than 60 years: urinary catheter-related bacteriuria in older adults is the most common infection (Touhy et al., 2012). Other nosocomial infections include surgical site infection, pneumonia, and blood stream infections. Prevention begins with hand hygiene and measures to minimize the risk of infection from procedures (see Chapter 32). Prevention also includes measures to increase the older adult's resistance to infection.

Older adults in acute care settings are also at risk for acquiring urinary incontinence (transient incontinence). Causes of transient urinary incontinence include delirium, untreated urinary tract infection, excessive urine production, medications, restricted mobility, and constipation or impaction. Interventions for transient urinary incontinence should be geared to correcting contributing factors. The interventions may include an individualized plan to provide voiding opportunities and modification of the environment to improve access to the toilet. Indwelling urinary catheters should be avoided if possible. Skin breakdown should be prevented.

The risk for skin breakdown and the development of pressure ulcers is increased by changes in aging skin and situations that arise in the acute care setting, such as immobility,

incontinence, and malnutrition. To prevent skin breakdown in older patients, you must avoid pressure on the skin, reduce shear forces and friction, provide skin care and moisture management, and provide nutritional support (see Chapter 42).

Older adults in the acute care setting are at risk for falling and sustaining injuries. Many of the falls occur as they get out of bed without assistance. Sedating medications may increase unsteadiness. Medications causing orthostatic hypotension may also increase the risk for falls because the blood pressure drops when the patient arises from a bed or chair. Diuretics increase the risk for falling because the adult must get out of bed often to void. Attempts to get out of bed when physically restrained may lead to injury if the patient becomes entangled in the restraint. Equipment such as wires from monitors, intravenous tubing, urinary catheters, and other medical devices become obstacles to safe ambulation. Impaired vision may prevent the patient from seeing tripping hazards such as garbage cans. Confused older adults, who may try to get out of bed although weak, unsteady, or drowsy, may benefit from the presence of family members and friends. Interventions to reduce the risk for falling include assistance with ambulation, strengthening exercises, medication monitoring, assistance with toileting, and removal of tripping hazards (see Chapter 36). Falls may be reduced by minimizing fall risk factors; through staff, patient, and family education; and through individualized fall-reduction interventions. The goal is to minimize the risk of falling without compromising mobility and functional independence.

Using the RNAO (2005a) best practice guidelines as a basis for falls prevention, a hospital in Ontario implemented a falls prevention strategy (Ireland et al., 2010) (Box 24-9).

Older Adults and Restorative Care

Restorative care consists of two types of ongoing care: (1) continuing the convalescence from acute illness or surgery that began in the acute care setting and (2) addressing chronic conditions that affect day-to-day functioning. Both types of care take place in private homes and long-term care settings.

Interventions during convalescence from acute illness or surgery are directed toward regaining or improving the prior level of independence in ADLs. Interventions that began in the acute care setting should be continued and later modified as convalescence progresses. To achieve this continuation, the acute care setting's discharge information should describe the ongoing interventions (e.g., exercise routines, wound care routines, medication schedules, vital sign monitoring, and blood glucose monitoring). To ensure that all the patient's needs are addressed, a team approach to discharge planning is important. Interventions should also address the restoration of interpersonal relationships and activities either at their previous level or at the level desired by the patient.

When restorative care addresses chronic conditions, the goals of care include stabilizing the chronic condition, promoting health, and promoting independence in ADLs. Interventions to stabilize the chronic condition may focus on regulation or prevention. An example of a regulatory intervention is the monitoring of blood glucose levels in diabetes. An example of promoting health is a smoking cessation program for the older adults with chronic obstructive pulmonary disease.

Health promotion interventions for older adults, as addressed in this chapter, should occur in all health care settings. For example, nurse-directed programs in long-term care settings improve ambulation, reverse urinary incontinence, and reduce confusion.

Interventions to promote independence in ADLs address physical ability, cognitive ability, and safety. The physical ability to perform ADLs requires strength, flexibility, and balance. Impairments of vision, hearing, and touch must be accommodated. The cognitive ability to perform ADLs requires the ability to recognize, judge, and remember. Cognitive impairments, such as Alzheimer's disease, may interfere with the safe performance of ADLs, although the affected patient is still physically capable of the activities. Interventions to promote independence in ADLs adapt these requirements to the needs and lifestyle of the older adult. Safety is always an important consideration. An older adult should be able to perform the ADLs with the least amount of risk.

Beyond the basic ADLs, the older adult's ability to perform instrumental ADLs must be assessed and appropriate interventions implemented. Instrumental ADLs are tasks such as using a telephone, preparing meals, shopping, doing laundry, cleaning the home, and driving an automobile. To remain independent at home or in assisted-living residences, older adults must be able to perform instrumental ADLs, be able to purchase services by outside workers, or have a supportive network of family and friends who assist with these tasks.

Restorative care measures focus on activities to prevent, improve, reduce, or eliminate problems. Priorities of care are established, patient goals and expected outcomes are determined, and appropriate interventions are selected. These are done with the patient's participation so that interventions are understood and conflicts in approaches or priorities can be avoided. An older adult's lifetime experiences, values, and sociocultural background are the bases for planning individual care. When deterioration of the patient's cognitive status prevents participation in care decisions, family or significant others must be consulted. Family and friends are rich sources of data because they knew the patient before the impairment. Frequently they can provide explanations for the older adult's behaviours and suggest methods of management. Thoughtful assessment and planning involve consideration of

BOX 24-9 RESEARCH HIGHLIGHT

Designing a Fall-Prevention Strategy That Works

Evidence Summary

A falls prevention strategy based on the RNAO (2005a) Best Practice Guidelines was implemented on 60 clinical units in an Ontario hospital. The strategy included a basic approach to falls risk assessment and a falls prevention education program for staff. At the end of the first year of implementation, 92% of staff had received the education. Compared to the previous year, there was a 20% reduction in falls hospital-wide.

Application to Nursing Practice

- The number of falls in a hospital can be reduced through implementation of a falls prevention strategy.
- Falls risk assessment is an important part of the strategy.
- Education of staff is an important part as well.

Reference: Ireland, S., Lazar, T., Mavark, C., Morgan, B., Pizzacalla, A., Reis, C., & Fram, N. (2010). Designing a falls prevention strategy that works. *Journal of Nursing Care Quality*, 25(3), 198–207.

the influence of normal aging changes, facilitate an optimal level of comfort and coping, and promote independence in self-care activities.

✦ KEY CONCEPTS

- The number of older adults, especially the number of older adults older than 85 years, is increasing.
- Because your attitudes toward older adults influence the quality of care, those attitudes should be based on accurate information about older adults, rather than on myths and stereotypes.
- Biological and psychosocial theories of aging offer possible explanations for the changes seen in aging, but every older adult is a unique individual who ages in a unique way.
- The physical changes that accompany aging are considered normal, not pathological, although they may predispose the older adults to disease.
- Cognitive impairment is not normal in older adults, and necessitates assessment and intervention.
- Cognitive impairment includes acute, potentially reversible disorders and chronic, irreversible, progressive disorders.
- Areas affected by psychosocial changes of aging include retirement, social isolation, change in housing, death, and sexuality.
- Nursing interventions for psychosocial concerns include therapeutic communication, touch, cognitive stimulation, reminiscence, and interventions to improve body image.
- The leading causes of death in the older population are cancer, heart disease, stroke, lung disease, accidents and falls, diabetes, kidney disease, and liver disease.
- Health promotion recommendations for older adults include good nutrition, regular exercise, smoking cessation, measures to reduce the risk for falls, and measures to reduce adverse medication reactions.
- Acute care settings increase older adults' risk for delirium, dehydration, malnutrition, nosocomial infections, urinary incontinence, and falls.
- Restorative nursing interventions, whether accomplished in the older adult's home or in long-term care institutions, stabilize chronic conditions, promote health, and promote independence in basic and instrumental ADLs.

✦ CRITICAL THINKING EXERCISES

1. Mr. Brown, 73 years old, has come to the clinic for a routine check of his blood pressure. It is normal (130/80 mm Hg). He says that he wants to do everything he can to stay healthy. What advice can you give on health promotion and disease prevention?
2. Mrs. Shephard's daughter has come with her to the clinic. She is concerned about her mother's memory. She tells you that her mother's memory has been excellent but has suddenly become poor. Two days ago, Mrs. Shephard phoned her daughter six times in two hours, asking where her husband (the late Mr. Shephard) was, and, when told of his death four years ago, Mrs. Shephard denied this fact. When her daughter arrived at her house to check on her, she found that Mrs. Shephard had emptied the contents of all the closets onto the floor and accused her daughter of theft. Her daughter brought Mrs. Shephard to her own home that night because of concern about Mrs. Shephard's safety. From the daughter's report, you suspect delirium (acute confusional state). What questions should you ask, and what areas should you assess to identify the possible causes of Mrs. Shephard's confusion?

3. A nursing colleague tells you that she does not know very much about assessing older adults, and she asks for some pointers on how to perform a thorough assessment. What advice can you give her about the process of geriatric assessment?

✦ REVIEW QUESTIONS

1. Two factors contribute to the projected increase in the number of older adults:
 1. Financial success and improved environment
 2. Fewer medical problems associated with aging
 3. Improved medication plan and increase in federal health care funding
 4. The aging of the "baby-boom" generation and the growth of the population segment older than 85 years
2. Which of the following is true about the theories of aging?
 1. Genetic changes are solely responsible.
 2. Environment is the main factor.
 3. No single theory explains aging.
 4. Disease causes a decline in function.
3. The three common conditions affecting cognition in older adults are
 1. Stroke, heart attack, and cancer of the brain
 2. Cancer, Alzheimer's disease, and stroke
 3. Delirium, depression, and dementia
 4. Blindness, hearing loss, and stroke
4. Sexuality is recognized as a factor in the lives of older adults; thus,
 1. Any expression of sexuality should be discouraged
 2. All older adults, whether healthy or frail, need to express sexual feelings
 3. An older adult's need for sexual expression decreases
 4. The need to touch and be touched is decreased
5. The libido does not decrease in older adults; however,
 1. Frequency of sexual activity may decline
 2. Physical changes do not usually affect sexual functioning
 3. The need to touch and be touched is decreased
 4. The sexual preferences of older adults are not as diverse
6. Visual acuity declines with age. Presbyopia is a progressive decline in
 1. Distinguishing between blues and greens and among pastel shades
 2. The ability to see in darkness
 3. The ability to focus on near objects
 4. Adaptation to abrupt changes from darkness to light
7. A common age-related change in auditory acuity is called
 1. Presbycusis
 2. Presbyopia
 3. Calcification
 4. Hypertrophy
8. Taste buds atrophy and lose sensitivity. Older adults are less able to discern
 1. Salty, sweet, sour, and bitter tastes
 2. Hot and cold temperatures
 3. Moistness and dryness
 4. Spicy and bland tastes

9. Changes in the musculoskeletal system lead to changes in the configuration of the thorax. This is known as
 1. Hypertrophy
 2. Calcification
 3. Presbycusis
 4. Kyphosis
10. Frontotemporal dementia has an insidious onset and progresses slowly. Early symptoms include
 1. Poor hygiene, lack of social tact, and sexual disinhibition
 2. More involvement in surroundings and social situations
 3. Fluctuating cognition and visual or auditory hallucinations (or both)
 4. Motor features of Parkinsonism

Self-Concept

Original chapter by Victoria N. Folsie, APN, PMHCN-BC, LCPC, PhD

Canadian content written by Judee E. Onyskiw, RN, MN, PhD

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Discuss factors that influence the following components of self-concept: identity, body image, and role performance.
- Identify stressors that affect self-concept and self-esteem.
- Describe the components of self-concept as related to psychosocial and cognitive developmental stages.
- Explore ways in which a nurse's self-concept and nursing actions can affect a client's self-concept and self-esteem.
- Incorporate research findings to promote evidence-informed practice for identity confusion, disturbed body image, low self-esteem, and role conflict.
- Examine cultural considerations that affect self-concept.
- Apply the nursing process to promote a client's self-concept.

key terms

Body image, p. 399	Role performance, p. 399
Identity, p. 398	Role strain, p. 403
Identity confusion, p. 402	Self-concept, p. 396
Role ambiguity, p. 403	Self-esteem, p. 400
Role conflict, p. 403	Sick role, p. 403

Self-concept is the mental image that one has of oneself. It is a composite of ideas, feelings, and attitudes that a person has about his or her own identity, worth, strengths, and limitations. Self-concept comprises several domains: social, emotional, physical, and academic. Self-concept affects how a person adapts to challenges, difficult situations, and relationships. Individuals with a positive self-concept are better able to cope with illness and stressful life circumstances and events. They are also more likely to choose healthy behaviours and participate in activities to promote their health and prevent illness.

Nurses care for clients with a variety of health problems that can threaten their self-concept. The loss of a bodily function, a decline in activity tolerance, and difficulty managing a chronic illness are all situations that can potentially affect a client's self-concept. Nurses need to assess clients to determine if they have a healthy self-concept and to develop nursing strategies to meet client's needs. Nurses play a key role in helping clients adjust to alterations in self-concept and in supporting components of self-concept that enable clients to cope with difficulties.

Figure 25-1 Participating in group activities can foster adolescents' self-esteem. **Source:** From Birchenall, J., & Streight, E. (2003). *Mosby's textbook for the home care aide* (2nd ed.). St. Louis, MO: Mosby.

Scientific Knowledge Base

The development of self-concept begins in early childhood and continues across the lifespan. Parents and other family members, as well as relationships with others, influence the development of a child's self-concept. Other factors that influence the development of self-concept are the child's gender, developmental stage, socioeconomic status, culture, and environment. In general, young children tend to rate themselves higher on measures of self-concept than they rate other children, which is perhaps a reflection of their egocentric view of the world. Self-concept becomes more clearly differentiated during the transition into puberty and during adolescence. Adolescence is a particularly critical time, when many factors affect self-concept (Figure 25-1). The adolescent experience appears to adversely affect girls more than boys (Birndorf et al., 2005). For girls, adolescence brings menarche, its associated symptoms, the development of breasts, and a gain in body fat. As a result, adolescent girls may be more sensitive to their appearance and how others view them. For boys, there are no sudden physical changes to indicate puberty. Maturational changes are generally regarded as more positive (Park, 2003).

In adulthood, men tend to report higher levels of self-esteem than do women. However, the exact magnitude of this gender difference and the way it varies across the lifespan remain unclear. Job satisfaction and job performance are linked to self-esteem. When individuals lose a job, they lose their position-related identity, and their self-perceptions may be altered or diminished. They may not be motivated to be active socially or may even become depressed. Underemployment also can affect role identity and self-esteem (McKee-Ryan, 2011). A developmental goal of adulthood is to establish a sense of self that is stable and transcends relationships and situations.

In older adults, the sense of self may be negatively affected by emotional and physical changes associated with aging (Robins et al., 2002). When older adults lose a partner or develop health problems, for example, they may experience negative changes in independence or social interaction. These changes may alter their self-concept and self-esteem.

Ethnic and cultural differences in self-concept and self-esteem have also been demonstrated across the lifespan, and research findings suggest that differences in the development

of self-concept may exist (Twenge & Crocker, 2002). To ensure an individualized approach to nursing care, nurses must be sensitive to factors that affect self-concept and self-esteem in diverse cultures.

Individuals' perceptions of themselves and of their health are closely related. Clients' beliefs about their personal health can enhance their self-concept. Statements such as "I can get through anything" or "I've never been sick a day in my life" indicate that a person's thoughts about personal health are positive. Self-concept is also affected by illness, hospitalization, and surgery. Chronic illness may affect the ability to provide financial support, thereby affecting an individual's self-esteem and perceived roles within the family. Negative perceptions regarding health status may be reflected in such statements as "It's not worth it anymore" or "I'm a burden to my family." Chronic illness can affect identity and body image. This is reflected in statements such as "I'll never get any better" or "I can't stand to look at my body this way."

What individuals think and how they feel about themselves affect the way they care for themselves physically and emotionally and the way they care for others. How a person behaves is generally consistent with both self-concept and self-esteem. Individuals who have poor self-concepts often do not feel in control of situations and may not feel worthy of care, which can influence decisions regarding health care. Knowledge of variables that affect self-concept is crucial for providing effective treatment.

Nursing Knowledge Base

Knowledge developed from medical and social sciences, humanities, and psychology, as well as knowledge from nursing research and clinical practice, is used to provide clients with evidence-informed practice. This broad knowledge base allows nurses to have a holistic view of clients, which promotes quality client care that best meets the self-concept needs of each client.

Development of Self-Concept

Individuals are not born with a self-concept. Rather, self-concept develops throughout the life span. In the 1960s, Erik Erikson (1963) introduced his theory of psychosocial development. Erikson hypothesized that individuals must negotiate eight stages as they progress through the lifespan. At each stage, individuals faced key tasks that they must master. Each stage builds on the tasks of the previous stage, and successful mastery of each stage leads to a positive sense of self (Box 25-1).

Most individuals master each stage; however, individuals can regress during times of major stress or illness. Nurses learn to recognize an individual's failure to achieve an age-appropriate developmental stage or an individual's regression to an earlier stage in a period of crisis. This understanding enables nurses to individualize care and determine appropriate nursing interventions. Self-concept is always changing and is based on the following:

- Sense of competency and mastery of prior and new experiences
- Perceived reactions of other people to own body
- Ongoing perceptions and interpretations of other people's thoughts and feelings
- Personal and professional relationships
- Collective beliefs and images one holds about oneself
- Academic and employment-related identity

► BOX 25-1

Self-Concept: Erikson's Developmental Tasks**Trust Versus Mistrust (Birth to Age 1 Year)**

Develops trust from consistency in caregiving and nurturing interactions of parents and others
Distinguishes self from environment

Autonomy Versus Shame and Doubt (Ages 1 to 3 Years)

Begins to communicate likes and dislikes
Is increasingly autonomous in thoughts and actions
Appreciates body appearance and function
Develops self through modelling, imitation, and socialization

Initiative Versus Guilt (Ages 3 to 6 Years)

Takes initiative
Identifies with a gender
Gains enhanced self-awareness
Increases language skills, including identification of feelings
Is sensitive to family feedback

Industry Versus Inferiority (Ages 6 to 12 Years)

Incorporates feedback from peers and teachers
Increases self-esteem with new skill mastery (e.g., reading, math, sports, music)
Experiences strengthening of sexual identity
Is aware of strengths and limitations

Identity Versus Role Confusion (Ages 12 to 20 Years)

Accepts body changes and maturation
Examines attitudes, values, and beliefs; establishes goals for the future
Feels positive about expanded sense of self
Interacts with people whom he or she finds sexually attractive or intellectually stimulating

Intimacy Versus Isolation (Ages Mid-20s to Mid-40s)

Has intimate relationships with family and significant others
Has stable, positive feelings about self
Experiences successful role transitions and increased responsibilities

Generativity Versus Self-Absorption (Ages Mid-40s to Mid-60s)

Accepts changes in appearance and physical endurance
Reassesses life goals
Shows contentment with aging

Ego Integrity Versus Despair (Ages Late 60s and Older)

Feels positive about own life and its meaning
Is interested in providing a legacy for the next generation

Components and Interrelated Terms of Self-Concept

A positive self-concept provides a sense of meaning, wholeness, and clarity. A healthy self-concept has a high degree of stability, generates positive feelings toward the self, and helps individuals adapt positively to stressors. There are many components of self-concept. Those particularly relevant to nurses are identity, body image, and role performance. Self-esteem is a closely related concept. The terms *self-concept* and *self-esteem* are often used interchangeably, but there is a distinction. Self-esteem stems from self-concept, and self-esteem influences self-concept. *Self-concept* is a descriptive term, whereas *self-esteem* is an evaluative term. In other words, identity asks the question "Who am I?" whereas esteem really focuses on "Am I worthy?" Nurses facilitate communication and ensure that the nursing care plan is individualized to meet each client's needs when these terms are used appropriately.

Identity. Identity involves the internal sense of individuality, wholeness, and consistency of a person over time and in various circumstances. Identity distinguishes us from others. Identity is influenced by age, gender, social class, ethnicity, and culture. Establishing an individual identity is an important developmental task from childhood to adolescence to young adulthood. Identity develops over time and ends in being a "unique person." A child learns culturally and socially accepted values, behaviours, and roles through observing other people and modelling their behaviour. Identity is often gained from self-observation and from what individuals are told about themselves (Stuart & Laraia, 2005). A child first identifies with parental figures and later with teachers, peers, and role models. To form an identity, a child must be able to integrate learned behaviours and expectations into a coherent, consistent, and unique whole (Erikson, 1963).

Sexuality is a part of one's identity. Gender identity is a person's sense of self as a man or as a woman and includes a person's sexual orientation. This image and its meaning depend on culturally determined values that are affected by socialization (see Chapter 22).

Religious faith also may foster identity formation through participation in traditions and rituals (Good & Willoughby, 2007; Sinclair & Milner, 2005; Smith, 2003a, 2003b). Associating with others in a religious community provides strong identity experiences that influence an individual's sense of self.

Racial or cultural identity develops from identification and socialization within an established group, as well as through the experience of integrating the response of individuals outside the cultural or racial group into a person's sense of self. Differences in ethnic identity (e.g., Vietnamese Canadian, Polish Canadian) exist through participation in traditions, customs, and rituals. The evolution of cultural identity may be challenging for some individuals. For example, the children of Chinese immigrants who are born in Canada may experience two different environments on a daily basis—a traditional Chinese home and a largely Caucasian school environment. First Nations peoples recognize the pivotal role of personal and cultural identity and have engaged in strategies to reclaim their culture by revitalizing their language and traditional practices (Usborne & Taylor, 2010, p. 895). A strong cultural identity generally is positively related to self-concept, self-esteem, and psychological health and well-being (Twenge & Crocker, 2002; Usborne & Taylor, 2010). Cultural differences in self-concept exist and may also demonstrate some age-specific trends (Box 25-2).

- Racial and ethnic identity
- Sexual identity
- Personality structure
- Perceptions of events that have an impact on the self
- Personal appearance and physical attractiveness
- Current feelings about the physical, emotional, and social self
- Self-expectations

* BOX 25-2 CULTURAL ASPECTS OF CARE

Racial and Cultural Background

Racial and cultural identity are important components of a person's self-concept. Early in growth and development, an individual develops a racial and cultural identity within the family context. As the individual grows, the cultural aspects of their self-concept may be reinforced through family, social, or cultural experiences. An individual's self-concept may be strengthened or challenged through political, social, or cultural influences experienced in school or work environments. Positive or negative cultural role modelling and past experiences also influence self-concept.

Implications for Practice

- To improve a client's self-concept, develop an open, nonrestrictive attitude when assessing for and encouraging cultural practices.
- Ask clients what they think is important to help them feel better or gain a stronger sense of self.
- Encourage cultural identity by individualizing hygiene practices, dietary choices, and clothing to meet each client's self-concept needs.

Body Image. Body image involves attitudes related to the body, including physical appearance, structure, or function. Feelings about body image include those related to femininity and masculinity, youthfulness, sexuality, health, and vitality. These mental images are not always consistent with a person's actual physical structure or appearance. Some body image distortions have deep psychological origins, such as those that occur in an eating disorder (e.g., anorexia nervosa). Other alterations occur as a result of situational events such as an amputation of a limb as a result of trauma or a scar due to surgery.

The majority of men and women experience some degree of body dissatisfaction, which can affect body image and overall self-concept. Disturbances in body image can be exaggerated when a change in health status occurs. The way other people view a person's body and the feedback offered are also influential. For example, a controlling, violent husband might tell his wife that she is ugly and that no one else would want her. Over time, with repeated humiliation and degradation, she may incorporate this devalued image into her self-concept.

Body image is affected by cognitive growth and physical development. Normal developmental transitions such as puberty or menopause can affect body image. Body image is influenced by hormonal changes during adolescence. The development of secondary sex characteristics and changes in body fat distribution affect an adolescent's self-concept. In the

Figure 25-2 An individual's appearance influences self-concept.

older adult, changes associated with aging (e.g., decreasing visual acuity and hearing) can affect body image.

Cultural and societal attitudes and values also influence body image. Culture and society dictate accepted norms for body image that can influence a person's attitudes (Figure 25-2). Values such as ideal body weight and shape, as well as attitudes toward body markings, piercing, and tattoos, are culturally based. In North American culture, people have been socialized to dread the aging process. Youth, beauty, and vitality are emphasized, as is apparent in television programs, movies, and advertisements. The media play an important role in creating and perpetuating unrealistic standards of thinness, youth, and physical attractiveness that is difficult or impossible for individuals to attain (Strahan et al., 2008). The media even influence women's eating behaviours (Strahan et al., 2007). Exposure to societal messages that reflect the sociocultural norm have a negative impact on women. Men also have been shown to be negatively affected by idealized media images (Strahan et al., 2006).

Body image depends only partly on reality. When physical changes occur, individuals may or may not incorporate these changes into their body image. For example, people who have experienced significant weight loss may not perceive themselves as thin and thus may have a distorted body image. Body image issues are often associated with impaired self-concept and self-esteem.

Role Performance. Role performance is the way in which individuals perceive their ability to carry out significant roles. Common roles include parent, child, spouse, employee, and student. Some roles are assumed for a limited amount of time (e.g., student or client role). An individual's perception of competency in a role may or may not match other people's evaluation. Roles that individuals follow in given situations involve socialization to expectations or standards of behaviour. Individuals learn behaviours that are approved by society through the following processes:

- **Reinforcement-extinction:** Certain behaviours become common or are avoided, depending on whether they are approved and reinforced or are discouraged and punished.
- **Inhibition:** An individual learns to refrain from certain behaviours, even when tempted to engage in them.
- **Substitution:** An individual replaces one behaviour with another, which provides the same personal gratification.

- **Imitation:** An individual acquires skills or behaviours by observing and then imitating the skills and behaviours of other members of the family or other social or cultural groups.
- **Identification:** An individual internalizes the beliefs, behaviour, and values of role models into a personal, unique expression of self.

Ideal societal role behaviours are often hard to achieve in real life. Individuals have multiple roles and personal needs that often conflict. For example, an individual may be a mother of small children, a child of elderly parents, a student, and an employee. Each role involves meeting certain expectations. To function effectively in multiple roles, a person must know the expected behaviour and values, desire to conform to them, and be able to meet the role requirements. Successful adults learn to distinguish between ideal role expectations and realistic possibilities. Fulfillment of these expectations leads to an enhanced sense of self. Difficulty or failure in meeting role expectations leads to deficits in the sense of self and often contributes to decreased self-esteem or altered self-concept.

Self-Esteem. Self-esteem is an individual's overall sense of self-worth or the emotional appraisal of self-concept. It represents the overall judgement of personal worth or value. Self-esteem is positive when a person feels capable, worthwhile, and competent (Rosenberg, 1965). Self-esteem is shaped by the individual's appraisals of how he or she is perceived by significant others.

According to Erikson (1963), young children begin to develop a sense of usefulness or industry by learning to act on their own initiative. Children's self-esteem is related to their personal evaluation of their effectiveness at school, within the family, and in social settings. The evaluation of other people such as parents, teachers, and peers has a profound influence on children's self-esteem.

Global self-esteem levels tend to be highest in childhood, possibly because children's sense of self is inflated by a variety of positive sources (Robins et al., 2002). Self-esteem tends to decline in adolescence. This may be partially understood in the context of maturational changes associated with puberty and increased expectations associated with the transition from primary to secondary school. This decline may also be associated with a shift to more realistic information about the self. Some gender differences exist in the adolescent years; for example, boys report greater self-esteem than do girls (Birndorf et al., 2005).

Several factors have been shown to be positively associated with self-esteem in adolescents: for example, family cohesion, greater number of siblings, parental support and social and emotional support from other adult role models (Gomez & McLaren, 2006; Gorbett & Kruczek, 2008; Park, 2003). Adults may foster self-esteem in adolescents by providing positive communication through supportive and caring relationships (Birndorf et al., 2005; Park, 2003). Other factors related to greater self-esteem include family income above the poverty level, safe and nurturing environments, and religious community. Participating in physical activity that is developmentally appropriate and enjoyable can lead to positive self-esteem in boys (Strong et al., 2005) and in girls (Schmatz et al., 2007).

Self-esteem levels rise gradually during adulthood and decline sharply in old age (Robins et al., 2002). In general, this pattern holds true across gender, socioeconomic status, and ethnicity. Erikson's (1963) emphasis on the generativity stage

(see Chapter 21) may explain the rise in self-esteem and self-concept in adulthood. The individual is focused on being increasingly productive and creative at work, while at the same time promoting and guiding the next generation. Other than childhood, the mid-60s represents the highest level of self-esteem across the lifespan. At around 70 years of age, self-esteem declines sharply, which, according to Erikson's theory of psychosocial development, reflects a diminished need for self-promotion and a shift in self-concept to a more modest and balanced view of the self (Robins et al., 2002).

safety alert Lower levels of self-esteem may increase adolescents' tendency to engage in risky behaviours (Biro et al., 2006; Wild et al., 2004). Adolescents are more likely than people of other ages to engage in practices harmful to their health. A decline in self-esteem in adolescence is often associated with an increased need for attention. This need for attention may be demonstrated in unsafe behaviours, such as premature sexual activity, unprotected sex, or substance abuse. In addition, adolescents may take more risks when they begin to drive. These risks threaten adolescents' health and have implications for health care interventions.

To better understand self-esteem, consider the relationship between a person's self-concept and the ideal self. The *ideal self* is a representation of the attributes the person would like to have—an image of the person ideally. The ideal self acts as a motivator that gives the individual an incentive for future behaviour—providing an image of what he or she wants to be or not be. The ideal self is also used as a standard to evaluate the actual self. The ideal self originates in the preschool years and develops throughout life. Early in life, parents set ideals for their children to have certain attributes such as honesty, intelligence, and success. Through socialization practices, children often internalize the ideals of their parents (Zentner & Renaud, 2007). The ideal self is also influenced by other factors such as school, peer relations, and the media. Self-evaluation is an ongoing mental process. In general, a person whose self-concept comes close to matching the ideal self has high self-esteem, whereas a person whose self-concept varies widely from the ideal self suffers from low self-esteem.

A positive sense of self-esteem is an important variable in determining how an individual functions in the world. A person's ability to contribute to society in a meaningful way often affects self-concept and self-esteem. Once established, basic feelings about the self tend to be constant, although they may fluctuate somewhat. A situational crisis may temporarily affect one's self-esteem. Individuals who are sick and unable to be involved in society may feel worthless. Accepting a client as an individual with worth and dignity can help maintain and improve the client's self-esteem.

Stressors Affecting Self-Concept

A self-concept stressor is any real or perceived change that threatens identity, body image, or role performance (Figure 25-3). A stressor challenges a person's adaptive capacities. The most important factor in determining an individual's response is the individual's perception of the stressor. The ability to re-establish balance is related to numerous factors, including the number, intensity and duration of the stressors, and health status (see Chapter 29). The normal process of maturation and development itself is a stressor. Changes that occur in physical, spiritual, emotional, sexual, familial, and sociocultural health

Figure 25-3 Common stressors that influence self-concept.

can affect self-concept. Being able to adapt to stressors is likely to lead to a positive sense of self, whereas failure to adapt may lead to a negative sense of self.

Any change in health can be a stressor that potentially affects self-concept. A physical change can alter body image, thereby affecting identity and self-esteem. Chronic illnesses often alter role performance, which may affect identity and self-esteem. Loss of a partner can lead to loss of identity and lower self-esteem (Van Baarsen, 2002). An essential process in adjusting to loss is the development of a new self-concept. The following case study illustrates the interrelationships among the various components of self-concept.

Amil, a 48-year-old man, has a sudden, unexpected stroke. He had not even been aware that he was hypertensive. Amil awakens in the hospital to find that he cannot move his right hand. He cannot care for himself and is unable to turn himself for days. With the nurses' and physiotherapists' constant encouragement, he is finally able to pull himself out of bed and into a chair. He wonders about the future. Amil's body image has dramatically changed. He used to think of himself as physically strong. Now, he feels weak and helpless. He worries about his family. His older child is away at college, and his younger child is still in high school. Although his wife works, they need both wages to meet their monthly expenses and to educate their children. If his condition does not improve, Amil's role as primary financial provider for his family will drastically change.

Amil's self-esteem diminishes as his recovery and rehabilitation progress slowly. His self-concept has changed from a person who is self-sufficient to someone who must rely on others. Although he returns home and is in rehabilitation, Amil is not able to perform tasks for his family and must wait until his wife and child get home to help him with activities that require strength. Although Amil's physician tells him that he is fortunate to be alive, his adaptation capabilities are stretched to the maximum. His identity is not clear

to him anymore. He has no clear role within the family, his body image has been radically altered, and his self-esteem is low.

Amil continues with physiotherapy. He requires significant time and energy even for simple tasks. Slowly, he begins to gain some strength. After months of rehabilitation and support from an interdisciplinary team of health care providers, he is able to return to work, with some modifications to ensure his safety. He has some diminished mental agility and muscle weakening, but he is able to perform most aspects of his job. His self-esteem and body image improves. Although he still feels somewhat weaker, his physical capabilities closely resemble those he had before the stroke.

Crisis occurs when a person cannot overcome obstacles with his or her usual methods of problem solving and adaptation. Any crisis potentially threatens self-concept and self-esteem. Some crises, such as the one described in the preceding case study, directly affect all components of self-concept. Self-esteem has been shown to be negatively affected by stroke, and this development is strongly associated with depressive mood (Vickery et al., 2008). The stressors created by a crisis—identity confusion, disturbed body image, low self-esteem, role conflict, role strain, role ambiguity, and role overload—may result in illness. For example, a diagnosis of cancer places additional demands on a person's established living pattern. It changes the person's appraisal of and satisfaction with the current level of physical, emotional, and social functioning. Learned resourcefulness, social support, and, in particular, self-esteem are predictive of health-related quality of life for long-term survivors of cancer (Pedro, 2001). Health-related quality of life may increase with interventions such as nurse-led support groups aimed at supporting and improving self-esteem. During self-concept crises, supportive and educative resources can help a person learn new ways of coping and responding

to the stressful event or situation in order to maintain or enhance self-concept.

Identity Stressors. Developmental markers such as puberty, menopause, retirement, and decreasing physical abilities may affect identity. Identity, like body image, is closely related to appearance and abilities. An individual's identity is affected by stressors throughout life, but it is particularly vulnerable during adolescence, a time characterized by physical, emotional, and mental changes of increasing maturity, which can result in insecurity and anxiety. It is also a time when adolescents are developing psychosocial competence, including coping strategies (see Chapter 29). A positive self-concept in adolescence enhances psychological and physical health in young adulthood (Box 25-3).

Adults generally have a more stable identity and thus a more firmly developed self-concept than do younger people. Cultural and social stressors, rather than personal stressors, may have more effect on an adult's identity. For example, an adult may have to balance career and family or make choices regarding religious or cultural traditions. Retirement may mean the loss of an important means of achievement and continued success. People at retirement may begin to re-evaluate

their identities and accomplishments. Loss of a significant other can lead the surviving individual to re-examine aspects of his or her identity.

Identity confusion results when people do not maintain a clear, consistent, and continuous consciousness of personal identity. It may occur at any stage of life if a person is unable to adapt to identity stressors. Under extreme stress, an individual may experience disturbed personal identity, a state in which the differences between the self and others cannot be determined. One example of identity confusion is when an adolescent realizes that some of his or her feelings and behaviours could be understood as homosexual. A period of anxiety and confusion begins, when the possibility of being homosexual clashes with a heterosexual self-image.

Body Image Stressors. Changes in appearance, structure, or function of a body part requires an adjustment in body image. An individual's perception of the change and the relative importance placed on body image affects the significance of the loss of function or change in appearance. For example, if a woman's body image incorporates reproductive functions as the ideal, a hysterectomy to treat uterine cancer may be a significant alteration and may result in a perceived loss of femininity or wholeness. Changes in body appearance, such as an amputation, facial disfigurement, or scars from burns or surgery, are physically obvious stressors affecting body image. Mastectomy and colostomy are surgical procedures that alter body appearance and function; although these changes are usually undetected by other people, they nonetheless have a significant effect on the individual. Even elective changes such as breast augmentation or reduction can affect body image. Chronic illnesses such as heart and renal disease affect body image because the body no longer functions at an optimal level. Anticipated body changes resulting from developmental processes can also affect body image. In addition, the effects of pregnancy, significant weight gain or loss, pharmacological management of illness, or radiation therapy change body image. Negative body image can lead to adverse health outcomes.

Many people associate success with a specific body part or function. For example, athletes may consider their bodies and physical activities to be the focus of personal success. Adaptation and rehabilitation may be affected if they can never again participate in athletics because of an accident or injury. To a surgeon, an amputation of a finger would significantly alter his or her ability to perform surgery. This change may affect the person's perception of his or her self-worth. Body image changes necessitate the revision of long-accepted self-perceptions, as well as alterations in lifestyle. To regain a positive self-concept and self-esteem, each person must adapt to his or her body image stressors.

Society's response to an individual's physical changes may be affected by the conditions surrounding the alteration. For example, in response to paralysis resulting from an act of war, an individual may be treated as a hero and may be praised for self-sacrifice. However, paralysis resulting from a car accident in which the person was intoxicated may elicit a very different response from society.

Role Performance Stressors. Throughout life, a person undergoes numerous role changes. Normal changes associated with growth and maturation result in developmental transitions. Situational transitions occur when parents, spouses, children, or friends die or when people move, marry, divorce, or change jobs. A health-illness transition is changing

* BOX 25-3 RESEARCH HIGHLIGHT

Adolescent Self-Concept and Health

Research Focus

The literature on adolescent self-concept is considerable, but little is known about the long-term effect of self-concept on health. By understanding the role of self-concept in adolescent health, you can develop strategies to promote adolescent health and design health education programs to meet the needs of this population.

Research Abstract

The purpose of Park's (2003) longitudinal study was to examine factors associated with adolescent self-concept and the effect of adolescent self-concept on psychological health, physical health, and health-related behaviour in later adulthood. Park analyzed data from two cycles of the National Population Health Survey, a general health survey of a representative sample of Canadians aged 12 years or older in the 10 provinces. The data revealed that girls tend to have lower self-concept in adolescence than do boys of the same age. A stronger self-concept was positively associated with higher family income and with adolescents' perceived level of emotional support. A weak self-concept was predictive of depression six years later among girls, physical inactivity among boys, and obesity among adolescents of both sexes. A strong self-concept had a positive long-term effect on girls' (but not boys') self-perceived health.

Evidence-Informed Practice

- Adolescent self-concept and self-esteem are important issues to be addressed in a variety of settings when adolescent health is promoted.
- Emotional support must be provided to adolescents, and they must be assisted in accessing emotional support from significant others in their lives.
- To strengthen health promotion policies and health education programs, strategies to enhance adolescents' self-concept and self-esteem should be included.

from a state of health or well-being to one of illness. A shift along the continuum from illness to wellness is as stressful as a shift from wellness to illness. Any of these transitions may lead to role conflict, role ambiguity, role strain, or role overload.

Role conflict results when a person simultaneously assumes two or more roles that are inconsistent, contradictory, or mutually exclusive. For example, when a middle-age woman with teenage children assumes responsibility for caring for her older parents, conflicts may arise in relation to being both the adult child and the caregiver of her parents. Role conflicts can occur when trying to balance time and energy between her children and parents. The perceived importance of each conflicting role influences the degree of conflict experienced. The **sick role** involves the expectations of other people and society about how a person should behave when sick. Role conflict may occur when general societal expectations (“Take care of yourself and you will get better”) and the expectations of co-workers (“The job needs to get done”) collide. The conflict of taking care of oneself while getting everything done can be a major challenge.

Role ambiguity involves unclear role expectations. When expectations are unclear, people may be unsure about what to do or how to behave. Such situations are often stressful and confusing. Role ambiguity is common in adolescence. Parents, peers, and the media pressure adolescents to assume adultlike roles, but many adolescents lack the resources to move beyond the role of dependent children. Role ambiguity can occur in employment situations. Employees may become unsure about job expectations in complex, rapidly changing, or highly specialized organizations.

Role strain is the stress or strain experienced by an individual when behaviours, expectations, or obligations associated with a single social role are incompatible. Individuals who feel inadequate or unsuited for a new social role may experience role strain. For example, individuals who marry someone with children often feel unprepared to assume the parental role. Role strain is also associated with gender role stereotypes (Stuart & Laraia, 2005). Some people perceive women in positions traditionally held by men as less competent, less objective, or less knowledgeable than their male counterparts. Women may feel that they must work harder and perform better in order to compete. Men in traditionally female roles may also encounter gender bias; for example, male nurses frequently report gender stereotyping by clients and other health care providers (Meadus & Twomey, 2007). One such stereotype suggests that male nurses are viewed as less caring than are female nurses.

Role overload involves having more roles or responsibilities within a role than are manageable. It is frequently reflected in unsuccessful attempts to meet the demands of work and family while still having some personal time. During periods of illness or change, the people involved, either as the person who is ill or as a significant other, often find themselves in role overload. Women are more likely than men to report high levels of role overload (Duxbury & Higgins, 2003). Findings from the 2005 National Survey of the Work and Health of Nurses in Canada shows that a disproportionately high number of nurses report role overload (e.g., arriving at work early or staying late to get work done). High role overload was more common among nurses in hospitals or long-term care facilities than among nurses working in community health, and more common among registered nurses (RNs) than

licensed practical nurses (LPNs) or registered psychiatric nurses (RPNs) (Statistics Canada, 2006).

Self-Esteem Stressors. Individuals with high self-esteem are generally more resilient and are better able to cope with demands and stressors than are those with low self-esteem. High self-esteem is associated with more optimal mental and physical health, greater control over circumstances, and greater adaptation and productivity in adulthood (Trzesniewski et al., 2006). Low self-worth can contribute to feeling unfulfilled and isolated from others and can result in depression and unremitting uneasiness or anxiety. Illness, surgery, or accidents that change life patterns can also influence feelings of self-worth. Chronic illnesses such as diabetes, arthritis, and cardiac dysfunction necessitate changes in accepted and long-assumed behavioural patterns. The more the chronic illness interferes with the ability to engage in activities contributing to feelings of worth or success, the more it affects self-esteem.

Self-esteem stressors vary with developmental stages. Perceived inability to meet parental expectations, harsh criticism, inconsistent discipline, and unresolved sibling rivalry may reduce children’s sense of self-worth. Ineffective parenting also is associated with low self-esteem in children. Low self-esteem takes a toll on children. Children with low self-esteem and self-worth are more likely to bully other children and are more likely to be bullied (Christie-Mizell, 2003; Box 25-4). Low self-esteem in adolescence is one of the strongest predictors of depression (MacPhee & Andrews, 2006) and is related to thoughts about suicide (Wilburn & Smith, 2005). A developmental milestone such as pregnancy also introduces unique self-concept stressors and has significant implications for health. Low self-esteem is one of the strongest predictors of postpartum depression (Beck, 2008). In older adults, self-concept stressors include health problems, reduced functional ability, and stressful life events and circumstances (Box 25-5).

The Family’s Effect on Development of Self-Concept

The family plays a key role in creating and maintaining each family member’s self-concept. Children develop a basic sense of who they are from their caregivers. Bowlby’s (1982) attachment theory suggests that the quality of the attachment that children develop with their caregivers influences the development of a set of expectations about the self, their interpretations of the actions of other people, and ideas about how to respond to them. Attachment theory suggests that children who experience sensitive and supportive caring will develop expectations that they are worthy of other people’s love and that other people are supportive. The quality of parenting interactions also influences children’s development. Parents who respond in a firm, consistent, and warm manner promote positive self-esteem in their children (Ruiz et al., 2002). Parents who are harsh, behave inconsistently, or have low self-esteem themselves may foster negative self-concepts in their children. Even well-meaning parents can cultivate negative self-concepts in children. To assist clients in developing a positive self-concept, it is important to assess the family’s style of relating (see Chapter 19).

The Nurse’s Effect on the Client’s Self-Concept

Your acceptance of a client with an altered self-concept helps promote positive change. When a client’s physical appearance

BOX 25-4 RESEARCH HIGHLIGHT

Bullying and Self-Concept

Research Focus

Bullying is defined as physical, psychological, or verbal intimidation or attack, or a combination of these, that is meant to cause distress, harm, or both to an intended victim. In Canada, approximately 15% of school-aged children report being bullied in the classroom, schoolyard, or playground. Some studies, however, indicate that bullying behaviour among children is increasing and is committed by younger children than in the past. Bullying is a serious problem both for the victims and the children who bully others.

One explanation for why children bully other children focuses on self-concept. Studies have shown that children with a positive self-concept are less likely to bully other children, engage in delinquent behaviour, or be instigators of peer conflict (Coloroso, 2002). In addition, children with a positive self-concept are less likely to be bullied. The family environment and, in particular, parenting behaviours influence children's self-concept.

Research Abstract

The objective of Christie-Mizell's (2003) study was to examine how the quality of the parental relationships (specifically, conflict between the parents) affects children's self-concept and participation in bullying behaviour. The researcher analyzed data from children aged 8 to 14 years who participated in the National Longitudinal Survey of Youth, a national survey of American children. The data revealed that participation in bullying behaviour is significantly tied to a child's self-concept. Lower self-concept was associated with an increase in bullying behaviour. In addition, the effect of parental conflict on children's bullying behaviour was mediated by the child's self-concept.

Evidence-Informed Practice

- Building children's self-concept is an important strategy to prevent bullying behaviour in children and to prevent being victimized by a bully.
- Parents must be helped to understand how children are affected by parental conflict and the family environment.
- It is important to involve the entire family system in the intervention process when children are identified as victims or bullies.
- Referral to other health care providers may be necessary to assist vulnerable children and families.

Reference: Christie-Mizell, C. A. (2003). Bullying: The consequences of interparental discord and child's self-concept. *Family Process, 42*(2), 237–251.

BOX 25-5 FOCUS ON OLDER ADULTS

- Promoting a positive self-concept in all older adults is essential, but it is especially important for those experiencing disability, frailty, or reduced functional capacity (Vickery et al., 2008).
- Conducting a life review or participating in a reminiscence group, recording an oral history, or making a photo scrapbook of meaningful life events are examples of activities to help older adults feel a sense of self-worth while providing a legacy for younger family members (Eliopoulos, 2005).
- Potential threats to the self-esteem of older adults may arise from the institutional environments where they receive care. These threats can include dependence, devaluation, depersonalization, functional impairments, and lack of control over one's environment. Nursing interventions directed toward reducing or eliminating these threats can improve older adults' quality of life.
- Self-concept may be negatively affected in older adulthood by a number of life changes, including health problems, reduced functional ability, declining income or socioeconomic status, spousal loss or bereavement, loss of social support, and decline in achievement experiences after retirement (Stuart & Laraia, 2005).
- Health care providers should be alert to older adults' preoccupation with physical complaints; they should conduct a comprehensive assessment and encourage clients to verbalize needs, feelings, and emotions such as fear, insecurity, and loneliness (Robins et al., 2002).
- By actively listening and accepting the person's feelings, being respectful, praising health-seeking behaviours, and recognizing, acknowledging, and praising accomplishments, health care providers convey respect for the older person's worth.

has changed, likely both the client and the family will observe your verbal and nonverbal responses and reactions. You need to be aware of your own feelings, ideas, values, expectations, and judgements. Self-awareness is critical in initially understanding and accepting others. Nurses who are secure in their own identities more readily accept and thus reinforce clients' identities. It is important to assess and clarify the following self-concept issues:

- Thoughts and feelings about lifestyle, health, and illness
- Awareness of how nonverbal communication may affect clients and families
- Personal values and expectations and how they affect clients
- Ability to convey a nonjudgemental attitude toward clients

- Preconceived attitudes toward cultural differences in self-concept and self-esteem

Some clients with a change in body appearance or function are very sensitive to health care providers' verbal and nonverbal responses. A positive and matter-of-fact approach to care can provide a model for the client and family to follow. You can have a positive effect by conveying genuine interest and acceptance. By recognizing and including self-concept issues in planning and delivering care, you can positively influence client outcomes. By building a trusting nurse–client relationship and appropriately involving the client and family in decision making, you can enhance self-concept. An individualized approach may highlight a client's unique needs, including incorporating alternative health care practices or methods of spiritual expression.

You also can significantly influence a client's body image. For example, for a woman who has undergone a mastectomy, you can affect her body image in a positive way by showing acceptance of the mastectomy scar. Clients closely watch other people's reactions to their wounds and scars. A facial expression of shock or disgust can lead to development of a negative body image. It is important to monitor your responses. Statements such as "This wound is healing nicely" or "The tissue looks healthy" are very affirming for a client. Nonverbal behaviours help to convey caring for a client and can affect self-esteem (Figure 25-4). For example, the self-concept of an

Figure 25-4 Nurses can use touch and eye contact to enhance a client's self-esteem.

incontinent client can be threatened by the perception that the caregivers find the situation unpleasant. Anticipate personal reactions, acknowledge them, and focus on the client instead of on the unpleasant task or situation. Imagining yourself in the client's position will help you find strategies and measures to ease your client's embarrassment, frustration, and anger.

Preventive measures, early identification, and appropriate treatment can minimize the intensity of self-esteem stressors and the potential effects on the client and family. Learn to design specific self-concept interventions to fit a client's profile of risk factors. It is essential to assess the client's perception of a problem and to work collaboratively with the client to resolve self-concept issues (Box 25-6). It may also be necessary to work with other members of the health care team to resolve issues related to self-concept.

Critical Thinking

Self-concept profoundly influences a person's response to illness. A critical thinking approach to care is essential. This approach requires synthesis of knowledge, experience, information gathered from clients and families, critical thinking qualities, and intellectual and professional standards. Solid clinical judgement requires anticipating the required information, collecting and analyzing the data, and making appropriate decisions regarding client care.

In the case of self-concept, it is essential to integrate knowledge from nursing and other disciplines, including self-concept theory and communication principles, and to consider cultural and developmental factors. Previous experience in caring for clients with alterations in self-concept assists you in individualizing care for each client. The nursing process continues until the client's self-concept is improved, restored, or maintained.

Self-Concept and the Nursing Process

❖ Assessment

In assessing self-concept, you must focus on the various components of self-concept: identity, body image, role performance, and self-esteem. Assessment should include observing behaviours suggestive of an altered self-concept (Box 25-7), actual and potential self-concept stressors (see the earlier case

Promoting a Healthy Body Image

Research Focus

In North American society, sociocultural norms for appearance suggest to girls and women that their value is determined by their appearance. The media typically play an important role in depicting women as thin, youthful, and beautiful. Women for whom this standard is unrealistic feel self-conscious and dissatisfied with their bodies. The extent to which women internalize society's standards for thinness is associated with body dissatisfaction and represents a risk factor for eating disorders.

Research Abstract

Strahan et al. (2008) tested whether sociocultural norms for ideal appearance leads women to base their self-worth more strongly on appearance. In the first study, the researchers presented images reflecting norms of thinness (e.g., one commercial featuring models wearing Victoria's Secret bras) to female university students; then they measured whether these images had a direct effect on the students' body satisfaction and concern with others' perceptions and whether appearance-contingent self-worth accounted for these effects. Results showed that exposure to images conveying the sociocultural norm for beauty influenced the students' perceptions of satisfaction with their bodies. The second study was conducted with students in public schools. Students received an intervention that challenged the legitimacy of sociocultural norms for ideal appearance. Results showed that in comparison with control subjects, students receiving the intervention were less accepting of sociocultural norms for appearance, based their self-worth less strongly on appearance, and in turn were less concerned with others' perceptions and were more satisfied with their bodies.

Evidence-Informed Practice

- Promoting empowerment, building self-esteem, and developing positive self-concept in girls and women are important health promotion strategies.
- Body weight concerns and coping strategies are important issues for nurses to address with girls and women.
- Nurses should increase clients' awareness of the role of the media and popular culture in promoting unrealistic and unhealthy standards.

Reference: Strahan, E. J., Lafrance, A., Wilson, A. E., Ethier, N., Spencer, S. J., & Zanna, M. P. (2008). Victoria's dirty little secret: How sociocultural norms influence adolescent girls and women. *Personality and Social Psychology Bulletin*, 34(2), 288–301.

study), and coping patterns. Nurses need to be sensitive to the effect that cultural influences have on the client's behaviours and needs. Some behaviours suggestive of an altered self-concept for someone in one culture may be normal for individuals in other cultures. For example, in many First Nations and Asian cultures, eye contact is a sign of disrespect. In order to gather comprehensive assessment, information from multiple sources must be synthesized critically (Figure 25-5).

At appropriate times, you will need to ask specific questions to assess your client's self-concept, paying close attention to your client's responses (Table 25-1). It is crucially important to closely observe nonverbal behaviour. Note the manner in which clients talk about significant people in their lives. This can provide clues to both stressful and supportive

Figure 25-5 Critical thinking model to assess self-concept.

► BOX 25-7

Behaviours Suggestive of Altered Self-Concept

- Avoidance of eye contact
- Slumped posture
- Unkempt appearance
- Being overly apologetic
- Hesitant speech
- Being overly critical or angry
- Frequent or inappropriate crying
- Negative self-evaluation
- Being excessively dependent
- Hesitancy in expressing views or opinions
- Lack of interest in what is happening
- Passive attitude
- Difficulty in making decisions

relationships, as well as to key roles that the client assumes. Using knowledge of developmental stages to determine what areas are likely to be important to the client, inquire about these aspects of the person's life. For example, ask an older client about his or her life and what has been important to him or her. At this stage of development, individuals are examining

► TABLE 25-1

Nursing Assessment of Client's Self-Concept

Assessment Questions*

Responses Reflecting Difficulties With Self-Concept

Identity

"How would you describe yourself?"

Derogatory answers (e.g., "I don't know; not too much is worth mentioning") should raise concern.

Body Image

"What aspects of your appearance do you like?"

Most people can identify something positive about their appearance (e.g., "I have nice eyes").

"Would you like to change any aspects of your appearance? If yes, describe the changes you would make."

If a person cannot identify any positive characteristic, this may suggest a negative body image and poor self-esteem. Most people have something that they would like to change (e.g., "My nose is too big" or "My hips are too large"), but a long list of problem areas may suggest difficulties with self-concept.

Self-Esteem

"Tell me about the things you do that make you feel good about yourself."

Statements about not having any strengths or being able to do anything well should raise concern.

"How do you feel about yourself?"

Statements that are very negative about themselves should raise concern (e.g., "I am hopeless" or "I have never felt good about myself").

Role Performance

"Tell me about your primary roles (e.g., partner, parent, friend, sister, employee, volunteer). How effective are you at carrying out each of these roles?"

Listen for the different roles identified. A large number of primary roles increase the risk for role conflict and role overload. As with previous questions, if the client indicates that he or she does not believe that these roles are adequately covered, the client may be experiencing alterations in self-concept. Most people carry out several roles and often feel as though some of them are not adequately addressed; listen for the client's perception about his or her overall role competency.

*In addition to the client's verbal response, note any nonverbal behaviours. A negative self-concept is suggested by hesitant speech, lack of interest in what is happening, and slumped posture.

their lives and considering the effects they have had in the world. The individual's conversation will probably provide data relating to role performance, identity, self-esteem, stressors, and coping patterns.

Coping Behaviours

Nursing assessment should also include consideration of previous coping behaviours; the nature, number, and intensity of the stressors; and the client's internal and external resources. Knowledge of how a client has handled past stressors can enable insight into the client's style of coping. People do not

address all issues in the same way, but they often use a familiar coping pattern for newly encountered stressors. As previous coping patterns are identified, it is useful to determine whether these patterns have contributed to healthy functioning or created more problems. For example, abused women sometimes use alcohol or drugs to cope with the abuse, but the use of these harmful substances only creates additional stressors (see Chapter 29).

Exploring resources and strengths, such as the availability of significant others or prior use of community resources, can be important when developing a realistic and effective plan. It is also critical to understand how a client views a situation. For example, older women may be more accustomed to changes in their health status because of the aging process in general, and experiencing heart disease may be one more aspect of growing older. On the other hand, a cardiac event occurring in middle age may be less expected and more problematic for women because of family and career responsibilities and may thus elicit greater anxiety.

Significant Others

Significant others can help identify changes in a client's behaviour that may suggest alterations in self-concept. These individuals may have insights into the client's way of dealing with stressors or knowledge about what is important to the client's self-concept. The way a significant other talks about the client and the significant other's nonverbal behaviours may provide information about what kind of support is available for the client.

Clients' Expectations

The client's expectations are another important factor to consider when assessing self-concept. Asking a client what he or she thinks you can do to help is important. Collaborating with clients is essential so that interventions are acceptable to them. Asking a client how he or she thinks the interventions will make a difference elicits useful information regarding the client's expectations and provides an opportunity to discuss the client's goals. For example, while working with a client who is experiencing anxiety related to an upcoming diagnostic test, you might ask about the relaxation exercise that he or she has been practising. The client's response provides valuable information about his or her beliefs and attitudes regarding the efficacy of the intervention, as well as the potential need to modify the nursing approach.

❖ Nursing Diagnosis

Carefully consider the assessment data to identify a client's actual or potential problem areas. Rely on knowledge and experience, apply appropriate professional standards, and look for clusters of defining characteristics that indicate a nursing diagnosis. Although multiple nursing diagnostic labels exist for altered self-concept, the following list provides examples of self-concept-related nursing diagnoses:

- *Impaired adjustment*
- *Anxiety*
- *Disturbed body image*
- *Caregiver role strain*
- *Decisional conflict*
- *Ineffective coping*
- *Ineffective denial*
- *Fearful*

► BOX 25-8 NURSING DIAGNOSTIC PROCESS

Assessment Activities	Defining Characteristics	Nursing Diagnosis
Observe client's behaviour during conversation.	Client demonstrates restlessness, inability to maintain eye contact, facial tension, increased perspiration, and self-preoccupation.	Anxiety related to accidental injury, pain, uncertainty of outcome of upcoming surgery
Empathically communicate, "Tell me how you are coping" or "How are you feeling about tomorrow's procedure?"	Client replies, "I'm scared. They may amputate my leg tomorrow. I don't know how I'll manage. I was awake all night. I just kept thinking about everything."	

- *Hopelessness*
- *Disturbed personal identity*
- *Risk for loneliness*
- *Ineffective role performance*
- *Chronic low self-esteem*
- *Situational low self-esteem*
- *Ineffective sexuality patterns*
- *Impaired social interaction*
- *Spiritual distress*
- *Risk for self-directed violence*

Making nursing diagnoses about self-concept is complex. Often, isolated data could be the defining characteristics for more than one nursing diagnosis (Box 25-8). For example, a client might express feelings of uncertainty and inadequacy. These are defining characteristics for both anxiety and situational low self-esteem. If the client is demonstrating defining characteristics for more than one nursing diagnosis, then gather specific data to validate and differentiate the underlying problem. To further assess the possibility of anxiety as the nursing diagnosis, you might consider whether the client has any of the following defining characteristics: Is the person experiencing increased muscle tension, shakiness, a sense of being "rattled," or restlessness? These symptoms may suggest anxiety rather than low self-esteem. On the other hand, if the person expresses a predominantly negative self-appraisal, including inability to handle situations or events and difficulty making decisions, then situational low self-esteem may be the more appropriate nursing diagnosis. To further aid in differentiating between the two diagnoses, information regarding recent events in the person's life and how the person has viewed himself or herself in the past provides insight into the most appropriate nursing diagnosis. As additional data are gathered, usually the priority nursing diagnosis becomes evident.

To validate critical thinking regarding a nursing diagnosis, it is important to share observations and allow the client to provide input and verify perceptions. This approach often encourages the client to provide additional data, which further clarifies the situation. In the example in Box 25-8, if you said,

"I notice you haven't eaten much lunch today," the response to this statement, coupled with the client's nonverbal communication, could facilitate further discussion. An alternative approach may be to state, "I notice you jumped when I came up behind you. Are you feeling uneasy today?" This statement allows the client to verify whether he or she is in fact anxious and to discuss any concerns.

❖ Planning

During planning, synthesize knowledge, experience, critical thinking qualities, and standards (Figure 25-6). Critical thinking ensures that the nursing care plan integrates all that you know about the individual, as well as key critical thinking elements (Box 25-9). Professional standards are especially important to consider when you develop a plan of care. These standards often establish ethical or evidence-informed practice guidelines for selecting effective nursing interventions.

Another method used to help plan nursing care is a concept map. The concept map illustrated in Figure 25-7 shows the relationship between a medical diagnosis, postoperative reconstruction of severe facial scars, and the four nursing diagnoses. The concept map also links the nursing diagnoses and shows how they are interrelated. In this example, disturbed body image is related to situational low self-esteem. As the client's facial scars improve, she should begin to feel better about her appearance.

Goals and Outcomes

In collaboration with the client, you should develop an individualized plan of care for each nursing diagnosis. Goals should be established that are individualized, are realistic, and have measurable outcomes. It is important to consult with the client about whether the goals are perceived as realistic. By consulting with the client and with significant others, mental health clinicians, and community resources, you can design a

Figure 25-6 Critical thinking model for self-concept planning.

► BOX 25-9 NURSING CARE PLAN

Disturbed Body Image

Assessment

You have been assigned to care for Ms. Johnson, a 45-year-old married woman who underwent a unilateral radical mastectomy because of malignancy. Ms. Johnson's physical assessment has been completed, and she has received adequate medication for pain. You sit down to discuss how the mastectomy has affected Ms. Johnson's self-concept.

Assessment Activities

Assess identity concerns (e.g., sexual role, femininity).

Findings and Defining Characteristics

Ms. Johnson looks away, shakes her head, and states, "I don't feel feminine. My husband says it won't affect how he feels about me, but I'm sure it will."

Ask Ms. Johnson how the mastectomy is affecting her sense of self.

Intermittent eye contact, frequent crying when alone, pulling hospital gown tightly across chest

Observe Ms. Johnson's mood and interactions with others, including family members.

Has superficial conversations with staff and family members

Determine Ms. Johnson's participation in self-care activities.

Avoids looking in mirror and touching or looking at the dressing; ignoring basic hygiene (e.g., bathing, combing hair, or brushing teeth)

Nursing Diagnosis: Disturbed body image related to negative thoughts and feelings to actual change in body

BOX 25-9 NURSING CARE PLAN—cont'd

Planning

Goal (Nursing Outcomes Classification)*

Ms. Johnson will identify and express feelings verbally and nonverbally.

Ms. Johnson will participate in self-care related to mastectomy.

Ms. Johnson will identify and use resources outside the hospital.

Expected Outcomes

Body Image

Ms. Johnson will discuss disturbed body image with staff members and significant others within 3 days. Ms. Johnson will consider exploring support groups by the time of discharge.

Acceptance and Health Status

Ms. Johnson will look at tissue surrounding surgical site within 2 days. Ms. Johnson will begin to attend to basic hygiene needs within 2 days.

Social Involvement

Ms. Johnson will verbalize commitment to participating in community resources (e.g., mastectomy support group) by the time of discharge. By postoperative visit, Ms. Johnson will determine whether she wishes to attend support group.

*Outcome classification labels from Moorhead, S., Johnson, M., Maas, M., & Swanson, E. (Eds.). (2008). *Nursing outcomes classification (NOC)* (4th ed.). St Louis, MO: Mosby.

Interventions (Nursing Interventions Classification)[†]

Initially assign the same staff members to work with Ms. Johnson.

Approach Ms. Johnson and initiate conversation; use silence and active listening to promote communication.

Remain aware of your own feelings regarding Ms. Johnson's bodily changes and physical appearance.

Have Ms. Johnson spend time alone and with supportive family members for crying, recording in her journal, reflection, or prayer.

Facilitate evaluation of overall self-concept.

Involve Ms. Johnson's husband in discussion of uncomfortable issues, such as sexual concerns.

Assist Ms. Johnson in identifying and using appropriate support systems outside the hospital, including home health care.

Rationale

Continuity in care will facilitate the establishment of a therapeutic relationship; familiarity and trust will enhance communication.

Ms. Johnson's ability to initially find the words for what she is experiencing may be limited.

Inadvertently communicating your own discomfort or negativity will interfere with Ms. Johnson's ability to openly communicate her feelings.

This use of time encourages expression of thoughts and feelings, including depression, grief, resentment, and fear of rejection. Family involvement is an essential element of comprehensive care.

The effect on body image may influence other aspects of self-concept and self-esteem, including perception of identity and role performance.

Sexuality is a basic need and concern for both men and women, and yet it can be one of the most difficult discussions for clients to initiate.

Support can assist the client in feeling normal again and in integrating a new body image into her self-concept.

[†]Intervention classification labels from Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St Louis, MO: Mosby.

Evaluation

Nursing Actions

Ask Ms. Johnson how effective she feels in her ability to identify and express feelings verbally and nonverbally.

Observe Ms. Johnson's participation in self-care related to mastectomy.

Assist Ms. Johnson in identifying resources outside the hospital; secure a commitment to use resources.

Client Response and Finding

Ms. Johnson responds, "It's hard for me to talk about myself, but I have really made an effort to talk about what the loss of my breast means to me."

Ms. Johnson assumes responsibility for basic hygiene immediately after establishing the goal and has used a mirror to examine her mastectomy scar.

Ms. Johnson verbalizes commitment to participating in community resources (e.g., mastectomy support group).

Achievement of Outcome

Ms. Johnson reports improvement in communication skills and success with discussing disturbed body image with primary nurse and husband.

Ms. Johnson has increased her independence and has begun to integrate body image change into her self-concept.

Outcome has not been completely achieved; Ms. Johnson has expressed hesitancy in attending a support group but is receptive to home care. Home care nurse will ensure that goal is re-evaluated and addressed as appropriate.

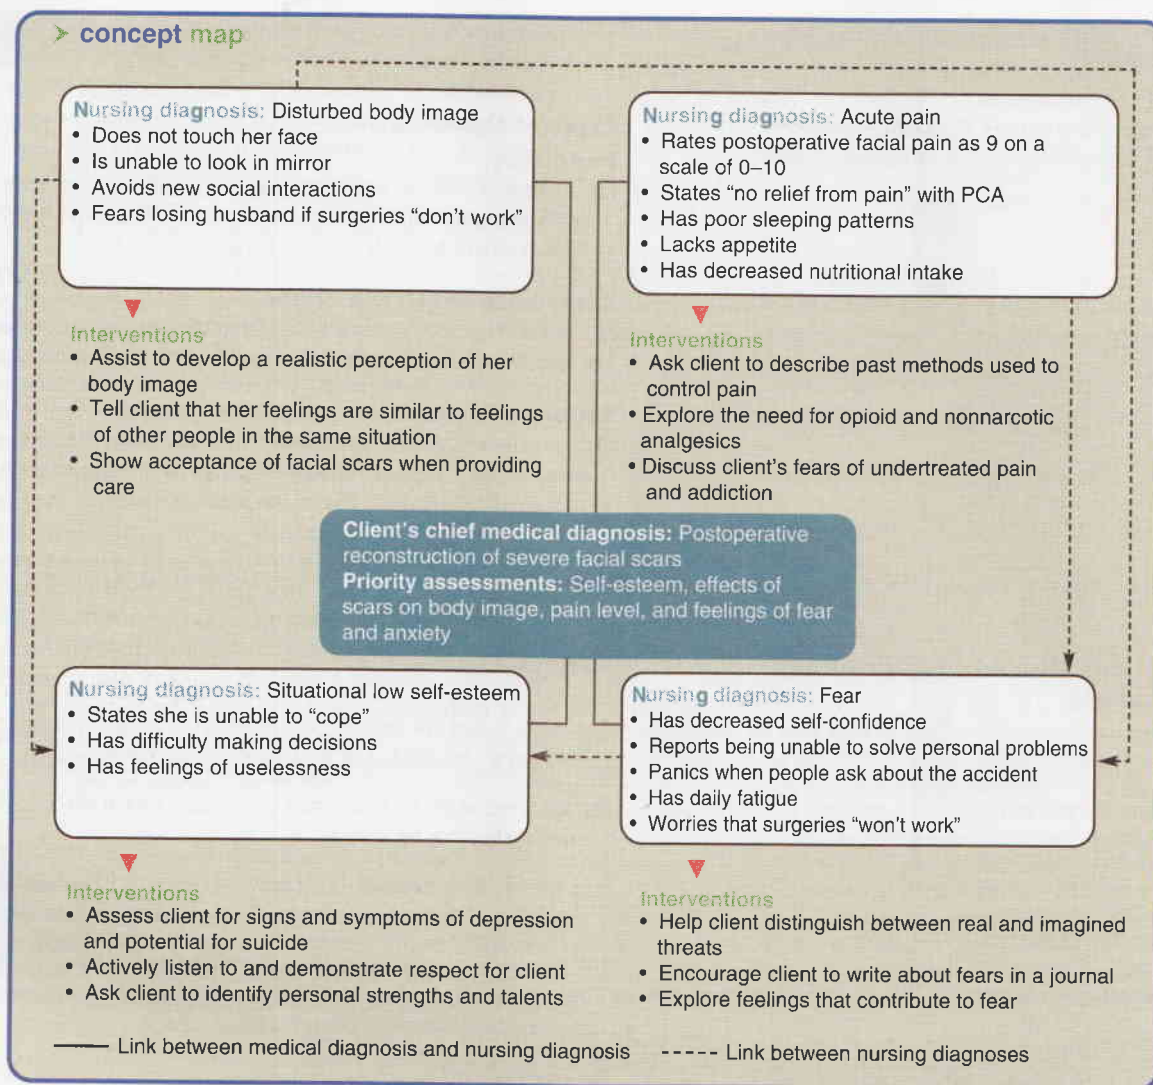

Figure 25-7 Concept map for client after surgical reconstruction of severe facial scars. PCA, Patient (client)-controlled analgesia.

more comprehensive and workable plan. Once a goal has been formulated, consider how the data that illustrated the problem would change if the problem were diminished. These changes should be reflected in the outcome criteria. For example, a client receives a diagnosis of *situational low self-esteem related to a recent job layoff*. You and the client establish a goal:

"Client's self-esteem and self-concept should begin to improve in two weeks." Examples of expected outcomes directed toward that goal include the following:

- The client will discuss a minimum of three areas of his or her life in which he or she is functioning well.
- The client will be able to voice the recognition that losing the job is not reflective of his or her worth as a person.
- The client attends a support group for out-of-work individuals.

Setting Priorities

The care plan lists the goals, expected outcomes, and interventions for a client with an alteration in self-concept. Interventions focus on helping the client adapt to the stressors that led to the disturbance in self-concept and on supporting successful

coping. A client may perceive a situation as overwhelming and may feel hopeless about returning to the previous level of functioning. The client may need time to adapt to physical changes.

Establishing priorities may include therapeutic communication to address self-concept issues to ensure that the client's ability to address physical needs is maximized. Look for strengths in both the client and the family, and provide resources and education to assist the client in changing limitations into strengths. Client teaching creates an understanding of the normality of certain situations (e.g., the nature of a chronic disease, change in a relationship, or the effect of a loss). Often, once this is understood, the sense of hopelessness and helplessness decreases.

Continuity of Care

The perceptions of significant others must be incorporated into the plan of care. Clients who have experienced deficits in self-concept before the current episode of treatment may have established a system of support that includes mental health clinicians, clergy, and other community resources. Before

involving the family, consider the client's desires for the family's involvement and cultural norms regarding who most frequently makes decisions in the family.

❖ Implementation

As with all the steps of the nursing process, a therapeutic nurse–client relationship is central to the implementation phase. Once the goals and outcome criteria have been developed, consider nursing interventions to promote a healthy self-concept and help the client move toward achieving the goals. To develop effective nursing interventions, consider the nursing diagnosis and broad interventions that address the diagnosis. These broad, standard interventions should be tailored to the individual client. Regardless of the health care setting, it is important to work with clients and their families or significant others to promote a healthy self-concept. For example, nursing interventions may include strategies to help clients regain or restore the elements that contribute to a strong and secure sense of self. The approaches that you choose will vary according to the level of care required.

Health Promotion

Work with clients to help them develop healthy lifestyle behaviours that contribute to a positive self-concept (Box 25-10).

Acute Care

In the acute care setting, some clients experience potential threats to their self-concept because of the nature of the treatment and diagnostic procedures. Threats to a person's self-concept can result in anxiety or fear. Numerous stressors,

including unknown diagnoses, the need to make changes in lifestyle, and change in functioning, may be present and need to be addressed. In the acute care setting, more than one stressor is often present, which increases the overall stress level for the client and family.

Nurses in the acute care setting also encounter clients who are faced with the need to adapt to an altered body image as a result of surgery, accidents, or other physical change. Sometimes, threats to self-concept and the need to adapt result in aggressive behaviour. Often a visit by someone who has experienced similar changes and adapted to them (e.g., someone who has undergone a laryngectomy or a mastectomy) may be helpful. The timing of such a visit is important. Because addressing these needs may be difficult while the client is in an acute care setting, appropriate follow-up and referrals, including home care, are essential. Remain sensitive to the client's level of acceptance. Forcing confrontation with the change before the client is ready could delay the client's acceptance. Signs that a client may be receptive to such a visit include the client's asking questions related to how to manage a particular aspect of what has happened or looking at the changed area. As the client expresses readiness to integrate the body change into his or her self-concept, let the client know about groups that are available, and make the initial contact.

Restorative Care

Often, in a long-term nurse–client relationship in a home care environment, nurses have the opportunity to work with clients to attain a more positive self-concept (Box 25-11). Interventions designed to help clients attain a positive self-concept are based on the premise that the client first develops insight and self-awareness concerning problems and stressors and then acts to solve the problems and cope with the stressors. This approach, outlined by Stuart and Laraia (2005), can be incorporated into client teaching for alterations in self-concept, including situational low self-esteem, which might manifest in the home care setting.

Increasing the client's self-awareness is achieved through establishing a trusting nurse–client relationship that allows the client to openly explore thoughts and feelings. A priority nursing intervention is the expert use of communication skills to clarify client and family expectations. Open exploration can make the situation less threatening and encourages behaviours that expand self-awareness. You encourage the client's self-exploration by accepting the client's thoughts and feelings, by helping the client clarify interactions with others, and by being empathetic. Encourage self-expression, and stress the client's self-responsibility. To promote the client's self-evaluation, help the client to define problems clearly, and identify positive and negative coping mechanisms. Work closely with the client to help analyze adaptive and maladaptive responses; contrast different alternative responses, and discuss outcomes.

Collaborating with the client in establishing realistic goals involves helping the client identify alternative solutions and develop realistic goals based on them. This collaboration facilitates real change and encourages further goal-setting behaviours. Design opportunities that result in success, reinforce the client's skills and strengths, and assist the client to obtain needed assistance. To assist the client in becoming committed to decisions and actions to achieve goals, teach the client to stop using ineffective coping mechanisms and develop successful coping strategies. Supporting attempts that are health

* BOX 25-10

FOCUS ON PRIMARY HEALTH CARE

Promoting Client's Self-Concept

The focus of primary health care is to promote health and prevent illness by stressing client education and self-care. Measures that contribute to a healthy self-concept and therefore promote health and well-being include those that support adaptation to stress, such as proper nutrition and regular exercise within the client's capabilities; those that facilitate adequate sleep and rest; and those that reduce stress.

Nurses are in a unique position to identify lifestyle practices that put a client's self-concept at risk or are suggestive of an altered self-concept. For example, a young adult visits a clinic with complaints of being unable to sleep and experiencing anxiety attacks. In gathering the health history, you may learn of lifestyle practices such as excessive use of alcohol or nonprescription drugs, too little rest, or a large number of life changes occurring simultaneously. These data, when taken together, may suggest actual or potential self-concept disturbances. In this situation, you determine how the client views the various lifestyle elements so that you can facilitate the client's insight into behaviours. If necessary, you provide needed health teaching or make appropriate referrals to other community services. Clients who are experiencing threats to or alterations in self-concept often benefit from mental health and community resources to promote increased awareness. Knowledge of available community resources enables you to make appropriate referrals.

BOX 25-11 CLIENT TEACHING

Alterations in Self-Concept

Objective

- Risks for situational low self-esteem will be reduced in the home care setting.

Teaching Strategies

- Reinforce the client's expression of thoughts and feelings; clarify meaning of verbal and nonverbal communication.
- Encourage opportunities for self-care.
- Elicit the client's perceptions of strengths and weaknesses.
- Convey verbally and behaviourally that the client is responsible for his or her own behaviour.
- Identify relevant stressors with the client, and ask for the client's appraisal of these stressors.
- Explore the client's adaptive and maladaptive coping responses to problems.
- Collaboratively identify alternative solutions; encourage the client to use alternatives not previously tried.
- Continue to reinforce the client's strengths and successes.

Evaluation

- Confirm the client's perception of and actual use of improved communication skills.
- Observe the client's level of participation in decisions that affect care.
- Confirm with the client and family that the increase in activities and tasks has been a positive experience.
- Observe the client's establishment of a simple routine.
- Observe the client take necessary action to change maladaptive coping responses and maintain adaptive responses.
- Confirm with the client and family how new coping resources can be applied to continued change.

Modified from Stuart, G. W., & Laraia, M. T. (2005). *Principles and practice of psychiatric nursing* (8th ed.). St Louis, MO: Mosby.

Figure 25-8 Critical thinking model for self-concept evaluation.

promoting is essential, because with each success, another attempt can be made. Supporting adaptive, flexible coping is crucial to help a client with an altered self-concept.

Establishing a therapeutic environment and a therapeutic relationship (see Chapter 17) and increasing self-awareness are also critical in successfully helping clients who have alterations in self-concept, whether care is focused on health promotion, dealing with an acute process, or addressing restorative care. To support a client in developing a positive self-concept, you must convey genuine caring (see Chapter 18) and establish a partnership with the client to address underlying problems.

❖ Evaluation

Client Care

Critical thinking is needed to evaluate success in meeting each client's goal and the established expected outcomes (Figure 25-8). Frequent evaluation of client progress is recommended so that changes can be instituted if necessary. You use knowledge of behaviours and characteristics of a healthy self-concept when you review the client's behaviours. This method determines whether outcomes have been met.

Expected outcomes for a client with a self-concept disturbance may include nonverbal behaviours indicating a positive

self-concept, statements of self-acceptance, and acceptance of change in appearance or function. Nonverbal behaviours can be key indicators of clients' self-concept. For example, a client who has had difficulty making eye contact may demonstrate a more positive self-concept by making more frequent eye contact. Social interaction, adequate self-care, acceptance of the use of prosthetic devices, and statements indicating understanding of teaching all indicate progress. A positive attitude toward rehabilitation and increased movement toward independence facilitate a return to preexisting roles at work or at home. Patterns of interacting can also reflect changes in self-concept. For example, a client who has been hesitant to express his or her views may more readily offer opinions and ideas as self-esteem increases. The goals of care may be unrealistic or inappropriate as the client's condition changes. The plan may need to be revised, to reflect on successful experiences with other clients. Client adaptation to major changes may take a year or longer, but such length is not suggestive of problems with adaptation. Look for signs that the client has reduced some stressors and that some behaviours have become more adaptive. Changes in self-concept take time. For some clients, the sense of hopelessness and helplessness may persist. Referral to other mental health specialists may be necessary.

Client Expectations

If you have a good rapport with the client, the client may be able to share how things are going from his or her perspective. You may be able to facilitate this sharing by initiating a review of what has happened over time. This offers the opportunity to share perceptions and encourages clients to consider and voice how they have conceptualized any changes.

❖ KEY CONCEPTS

- Self-concept is an integrated set of conscious and unconscious attitudes and perceptions about the self.
- Components of self-concept are identity, body image, and role performance.
- Each developmental stage involves factors that are important to developing a healthy, positive self-concept.
- Identity is particularly vulnerable during adolescence.
- Body image is the mental picture of a person's own body and is not necessarily consistent with a person's actual body structure or appearance.
- Body image stressors include changes in physical appearance, structure, or functioning that are caused by normal developmental changes or illness.
- Self-esteem is the emotional appraisal of self-concept and reflects the overall sense of being capable, worthwhile, and competent.
- Self-esteem stressors include developmental and relationship changes, illness (particularly chronic illness involving changes in what were normal activities), surgery, accidents, and the responses of other individuals to changes resulting from these events.
- Role stressors, including role conflict, role ambiguity, and role strain, may originate in unclear or conflicting role expectations and may be aggravated by illness.
- Your self-concept and nursing actions can have an effect on a client's self-concept.
- Planning and implementing nursing interventions for self-concept disturbance involve increasing the client's self-awareness, encouraging self-exploration, aiding in self-evaluation, helping formulate goals for adaptation, and assisting the client in achieving those goals.

❖ CRITICAL THINKING EXERCISES

1. You are assigned to care for a 23-year-old Chinese Canadian client who sustained multiple fractures to his face and femur four days ago in a motor vehicle accident. He had surgery the evening of admission to repair his femur but was admitted to wait for surgery to his face. The client lives with his girlfriend and their seven-month-old daughter and works as a janitor in the local university. He left China with his mother when he was a young child and has grown up in Canada. You have been with him for most of the morning. He was given an analgesic for his pain. His pain rating decreased from 6 to 3 on a scale of 0 to 10, but the morphine left him drowsy. During the morning, he shared with you some of his concerns about when he will be able to return to work. You are in the room when the surgeon tells him about his upcoming surgery. A temporary tracheotomy is planned because of the extensive surgery needed in the nasal and throat area. After the surgeon leaves, the client tells you that he does not want the tracheotomy. He indicates that he is unclear about what it actually entails, even though the surgeon explained it in fairly simple terms. He states, "I just want to get back to normal." How would you address this comment and his lack of understanding regarding the tracheotomy?
2. A 16-year-old girl is preparing for discharge from the hospital after giving birth a day earlier. She is unmarried, is uninvolved with the baby's father, and has minimal support from her family to help her care for her newborn. Before admission, she arranged to give the baby up for adoption. She reaffirms this as a good decision because she will be able to return to school

and still graduate with her peers. The client confides in you that her biggest concerns right now are how she feels about herself and how she looks. Taking into account the developmental needs of this adolescent, how will you collaborate with her to establish priority interventions to address her self-concept difficulties?

3. As a part of your community health experience, you are assigned to visit a 75-year-old woman who has gone to live with her daughter after being hospitalized for agitation and aggression secondary to Alzheimer's disease. When you go to their home, you find the 55-year-old daughter tearful. She says, "I just don't know if I can do this. She is so confused. She calls me two or three times a night but often doesn't recognize me when I come to her. I've been missing a lot of work. Even when I'm there, I'm not as productive because I'm so tired." What additional assessment data would be important to gather? What provisional nursing diagnosis could be made for the daughter?

❖ REVIEW QUESTIONS

1. When a nurse is caring for a client after mastectomy, interventions to promote physiological stability and pain control are necessary. What other nursing interventions would the nurse need to develop?
 1. Interventions to improve the client's mobility
 2. Interventions to improve the client's self-concept
 3. Interventions to improve the client's activity tolerance
 4. Interventions to improve the client's ability to perform self-care activities
2. Which of the following ages are associated with the self-concept developmental task of developing self through modelling, imitation, and socialization?
 1. 0 to 1 year
 2. 1 to 3 years
 3. 3 to 6 years
 4. 6 to 12 years
3. Which of the following involves the internal sense of individuality, wholeness, and consistency of a person over time and in various circumstances?
 1. Body image
 2. Self-concept
 3. Role performance
 4. Identity
4. Adolescents are at risk for body image disturbance. Which of the following is an accurate statement about body image?
 1. Body image is not influenced by the opinions of others.
 2. Body image refers to the external features of a person.
 3. Body image includes actual and perceived perceptions of one's body.
 4. Physical changes during adolescence are quickly incorporated into the person's body image.
5. What is the name of the process when certain behaviours become common or are avoided, depending on whether they are approved and reinforced or are discouraged and punished?
 1. Reinforcement-extinction
 2. Inhibition
 3. Substitution
 4. Identification

6. What is the name of the process when an individual internalizes the beliefs, behaviour, and values of role models into a personal, unique expression of self?
 1. Reinforcement-extinction
 2. Inhibition
 3. Substitution
 4. Identification
7. What age group is particularly vulnerable to stressors that can affect an individual's identity because that age is a time of great change?
 1. Infants
 2. Children
 3. Adolescents
 4. Adults
8. What is the possible outcome when a person does not maintain a clear, consistent, and continuous consciousness of personal identity?
 1. Identity confusion
 2. Low self-esteem
 3. Low self-concept
 4. Body image difficulties
9. What is the nurse assessing for when she or he asks the client, "How do you feel about yourself?"
 1. Identity
 2. Body image
 3. Self-esteem
 4. Role performance

10. Which of the following would help increase a client's self-awareness?
 1. Establishing a trusting nurse-client relationship that allows the client to explore his or her thoughts and feelings
 2. Accepting the client's thoughts and feelings
 3. Helping the client to define his or her problems clearly
 4. Having the client identify his or her positive and negative coping mechanisms

+ RECOMMENDED WEB SITES

Canadian Mental Health Association: Children and Self-Esteem: http://www.cmha.ca/bins/content_page.asp?cid=2-29-68

This Web page offers advice about how to promote positive self-esteem in children.

The Canadian Women's Health Network: Body Image and the Media: <http://www.cwhn.ca/resources/faq/biMedia.html>

This site contains a discussion of the impact of the media on body image, and it provides advice to help young women have a healthy body image.

Statistics Canada: Adolescent Self-Concept and Health Into Adulthood: <http://www.statcan.gc.ca/pub/82-003-s/2003000/pdf/82-003-s2003005-eng.pdf>

In this report, published in 2003, factors associated with adolescent self-concept are examined, and the effect of adolescent self-concept on later health and health-related behaviour in young adulthood is described.

Sexuality

Original chapter by Kathy Lever, MSN, WHNP-C

Canadian content written by Anne Katz, RN, PhD

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Discuss the nurse's role in maintaining or enhancing a patient's sexual health.
- Discuss the complexities of sexual identity, gender identity, and sexual orientation.
- Describe key concepts of sexual development across the lifespan.
- Describe the sexual response cycle.
- Identify high-risk and safer sex behaviours.
- Identify common sexually transmitted infections (STIs).
- Identify major types of sexual dysfunction and potential causes.
- Assess a patient's sexuality.
- Define appropriate nursing diagnoses for patients with alterations in sexuality.
- Identify and describe nursing interventions to promote sexual health.
- Evaluate a patient's sexual health.
- Identify potential referral resources for patients' sexual concerns outside the nurse's level of expertise.
- Use critical thinking skills to assist patients in meeting their sexual needs.

Sexuality and its expression are vital elements to the wholeness we feel as human beings. **Sexuality** is seen as “a central aspect of being human throughout life and encompasses sex, gender, identities and roles, sexual orientation, eroticism, pleasure, intimacy, and reproduction” (Wagner et al., 2005). People's view of themselves and others as sexual beings is influenced by their cultural, ethnic, and religious beliefs and practices. Sexuality also concerns people's sexual relationships with others and how they are perceived by others (van der Riet, 1998). Sexual functioning is seen as what people *do* as sexual beings; it is thought to consist of the four phases of the sexual response cycle as conceived by Masters and Johnson (1966; Barton et al., 2004). Sexual functioning, according to this definition, is the same as sexual behaviour; sexual dysfunction is thought to occur when behaviour does not follow some predetermined path and is seen as wrong or abnormal or necessitating intervention.

The World Health Organization (2004) defined **sexual health** as “a state of physical, emotional, mental and social well-being related to sexuality; it is not merely the absence of disease, dysfunction or infirmity. Sexual health requires a positive and respectful approach to sexuality and sexual relationships, as well as to the possibility of having pleasurable and safe sexual experiences, free of coercion, discrimination and violence. For sexual health

to be attained and maintained, the sexual rights of all persons must be respected, protected and fulfilled.”

Nurses have a role in the promotion of positive, healthful sexuality for youth, adolescents, young and middle-aged adults, and older adults. Nurses can also educate patients to help prevent adverse outcomes such as unwanted pregnancy, **sexually transmitted infections (STIs)**, or sexual dysfunction (Health Canada, 2008).

Religious teachings, culturally prescribed gender roles, beliefs about sexual orientation, and social and environmental climates influence both the patient's and the health care provider's value systems. You need to explore your own beliefs and prejudices and strive to develop a nonjudgemental and caring approach that integrates sexual health care into everyday practice.

Scientific Knowledge Base

To assist patients in meeting their sexual needs, you must have a sound scientific knowledge base about sexual and gender identity, sexual orientation, sexual development, the sexual response cycle, high-risk and safer sex behaviours, STIs, contraception, and abortion.

Sexual and Gender Identity

Sexual identity is the objective labelling of a person as male or female. Most people would probably say that two sexes exist and that sexual identification is fairly straightforward. Conventional wisdom is that a person's genitalia determine whether the person is male or female (Vilain, 2004). According to the XY sex-determination system, the two sex chromosomes are the same in female humans (XX) and different in male humans (XY). However, people do not always fit neatly within these systems of sexual identification. Variations in genitalia, gonads, chromosomes, or hormones occur in an estimated 17 of 1000 births in Canada (Johnson, 2004). For example, some people are born with ambiguous genitalia, which makes determining the sex of the infant difficult. Several genetic conditions can disrupt development of the fetus in such a way that the baby is neither fully male nor fully female (Liao, 2003). A child with an **androgen disorder** may have male-appearing genitalia and might **genetically** be a girl; another child might have male hormones and the external appearance of a girl.

Gender identity is the degree to which a person identifies as male, female, or some combination. It begins in early childhood as the child becomes aware of the differences of the sexes and perceives that he or she is male or female. Gender identity is usually consistent with physical sex at birth; however, this is not always the case. For example, in **transsexuality**, the physical body is incongruous with the gender identity. A transsexual person may have a female body but feel like a man or may have a male body but feel like a woman (Johnson, 2004). Current research findings indicate that gender identity disorder is caused by hormonal fluctuations at a crucial time in fetal development (Society for Human Sexuality, 2004). Many transsexual people choose to undergo sex reassignment so that their physical sex is congruent with their gender identity; this process involves surgery and the administration of hormones.

Sexual Orientation

Sexual orientation describes the predominant gender preference of a person's sexual attraction over time. **Heterosexuality**

is sexual preference for members of the opposite sex; **homosexuality** is sexual preference for members of the same sex. **Bisexuality** is an equal or almost equal preference for both sexes. In a recent Statistics Canada (2008) survey, 1.9% of Canadians aged 18 to 59 (2.1% of men and 1.7% of women) identified themselves as gay or lesbian, and about 0.9% of respondents identified themselves as bisexual. As a nurse, you must not assume that you know your patients' gender identity or sexual orientation. Anyone could be lesbian, gay, bisexual, transsexual, or heterosexual. If you learn a patient's sexual orientation, you should not assume that you may tell anyone else or include it in the medical record without the patient's knowledge. Some people might want to keep their sexual orientation confidential.

Earlier thinking about sexual orientation led many to believe that heterosexuality was normal and mentally healthy and that all other orientations were abnormal or signs of a psychological disorder. Today, this theory is summarily rejected; scientists agree that homosexuality, transsexuality, and bisexuality are not disorders and are not associated with mental illness or abnormal psychological functioning. Nevertheless, **homophobia**—the prejudicial treatment of or negative attitudes about lesbian, gay, bisexual, or transsexual people and those who are perceived to have these gender or sexual identities—still exists. Homophobia can include a range of emotions and behaviour from discomfort, fear, and disgust to hatred and violence. If you are nonjudgemental and equipped with an appropriate knowledge base, you can help address the problems of homophobia and provide nursing care that does not discriminate against the patient's sexual orientation.

Sexual Development

As a person grows and develops, so does his or her sexuality. Each stage of development brings changes in sexual functioning and in the role of sexuality in relationships.

Infancy and Childhood. The awareness of one's sexual identity and sexual development begins in infancy, when attitudes about the physical body are communicated by caregivers (Haroian, 2000). From birth on, children are treated differently according to their gender. The differential treatment shapes the behaviour of the child. During the school years, children expand their horizons from parents and family. Parents, teachers, and the child's peer group serve as role models and teach about how men and women act and relate with each other. School-aged children generally have questions regarding physical and emotional aspects of sex (Finan, 1997). They need accurate information from home and school about physical and emotional changes during this period and what to expect as they move into puberty. This knowledge may help decrease anxieties as changes begin to happen. An uninformed child may be frightened by menstruation or nocturnal emission and view them as evidence of a dreadful disease.

Puberty and Adolescence. Puberty is characterized by the development of secondary sex characteristics; in girls, these changes generally begin between the ages of 8 and 11 years. The first signs are usually the development of breast buds and, later, growth of pubic hair. The labia begin to enlarge, as do the internal reproductive organs. Sometime after the tenth year, the girl may experience her first menstrual period, and her body shape takes on a more womanly form. By the time she has her period, the breasts are usually fully developed, and pubic hair and axillary (underarm) hair are present. Over time, the menstrual cycle ordinarily becomes regular.

Figure 26-1 Adolescents function within a powerful network of peers as they explore their sexual and gender identity.

In boys, the changes usually occur about a year later. In some boys, starting at about age nine years, the testicles begin to enlarge, and the skin of the scrotum becomes darker and coarser. Pubic hair appears and the boy grows taller and more muscular. Genital growth continues over the next two years, and the boy begins to look like a male adult, with broad shoulders and narrow hips. When the larynx enlarges, the voice begins to deepen. Fine facial hair and axillary hair also begin to grow. Over time, pubic hair becomes coarser, and penile growth starts to slow down; the testicles continue to grow until they reach full size. Many boys between the ages of 15 and 19 years experience ejaculation, either spontaneously at night (nocturnal emission) or as a result of masturbation. By the end of puberty, the young man is close to his adult height, but further growth can occur into the third decade.

This is a developmental period in which social and emotional changes are also significant. Peer group attachments are strong; sexual attraction to other people is common (Figure 26-1). These emotional and social changes do not always keep up with the physical changes; as a result, an adolescent may look like an adult but still acts and thinks like a child. Perception of body image is important through this stage. Many adolescents are very unhappy with the way they look. They may constantly compare themselves with their peers or with images in the media, and they may consequently experience great dissatisfaction. Self-esteem may be affected negatively; low self-esteem may result in dangerous social and sexual behaviours. Cognitive changes that occur during adolescence are the ability to think in an abstract manner and to anticipate potential consequences (Duncan et al., 2003). These changes are useful in view of the physical and emotional changes.

It is the norm for youth, rather than the exception, to experiment sexually and often with multiple partners (Beitz, 1998); thus, it is essential that youth have access to sexual health services, including information on topics such as body changes, sexual health promotion, STIs, contraception, and pregnancy. Such services are designed to promote sexual health and to encourage responsible decision making with regard to sexual behaviour.

Public health care providers have been alarmed by the trend toward greater sexual activity at increasingly younger ages, particularly because of the adverse consequences. In 1998 in Canada, 21,000 girls between 15 and 19 years of age had elective abortions, and almost 20,000 girls of that age group

gave birth; these statistics translate into a rate of 19.8 births for every 1000 girls (Canadian Institute of Health Information, 2004). After teenage pregnancy, mothers and their children often experience health, financial, and social problems (Jewell et al., 2000). Similarly, exposure to STIs and unwanted sexual activity can lead to psychological disturbances, impairments in the development of healthy social and interpersonal relationships, and long-term physical health problems.

You may be most effective in your goals to support teenagers by helping parents develop confidence in educating their children about sexuality. Factual information regarding sexuality and sexual activity is important, but equally or perhaps more important is guidance in establishing a personal value or belief system to use as a framework for decision making. In healthy family networks, much of this guidance is conveyed in the course of child-rearing. Parents need to understand the importance of providing information, sharing their values, and promoting sound decision-making skills. Parents and significant others need to be counselled that even with the best guidance and information, adolescents will make their own decisions and must be held accountable for those decisions.

Adolescence is often a time when individuals explore their primary sexual orientation. Some teenagers may recognize their preference as distinctly homosexual, which can be frightening and confusing. Support for the adolescent's sexual identity is important during this time and can come from a variety of sources, such as school counsellors, clergy, family, and health care providers.

Adulthood. Adults have matured physically but continue to explore and define emotional maturation in relationships. Intimacy and sexuality are issues for all adults of all sexual orientations, whether they are in a sexual relationship, choose to abstain from sex, are single, are widowed, are divorced—whatever circumstances arise. People can be sexually healthy in numerous ways.

As sexually active adults develop intimate relationships, they need to learn techniques of stimulation that are satisfying to both themselves and their sexual partners. Some adults may need confirmation that alternative ways of sexual expression other than penile-vaginal intercourse are normal. Other individuals may require significant education or therapy to achieve mutually satisfying sexual relationships.

Through middle adulthood, physical changes can affect sexual functioning. Decreasing levels of estrogen in perimenopausal women (during the years leading up to menopause) and menopausal women (after menstruation has ceased) may result in diminished vaginal lubrication and decreased vaginal elasticity. Both of these changes may lead to **dyspareunia**, which is painful intercourse. Declining levels of testosterone result in decreased desire for sexual activity. Suggestions such as using vaginal lubrication and creating time for caressing and tenderness can help patients adjust to normal changes related to aging.

As men age, they are likely to experience an increase in the post-ejaculatory refractory period, delayed ejaculation, and erectile dysfunction. Advising patients of these normal changes related to aging can ease concerns regarding functioning. Aging adults may also need to adjust to the effects of chronic illness, medications, aches, pains, and other health concerns that affect sexuality.

Older Adulthood. As people age, some shift their priority from genital sex to other ways of expressing sexual desire. Activities that promote affection, romance, intimacy, and

Figure 26-2 Intimacy and affection are important to older adults. **Source:** From Sorrentino, S. A. (2004). *Mosby's Canadian textbook for the support worker* (p. 166). Toronto: Elsevier.

companionship may be enough to satisfy the sexual needs of some older adults (Figure 26-2). However, not all older adults experience a decline in interest in sex. The majority of people have the capacity to stay sexually active into very late life and regard sexual activity as important to their overall well-being and quality of life (Gott, 2001). Aging does, however, affect sexual functioning (Box 26-1). The accompanying psychological and physical transitions require flexibility in thinking and adjustment to the changes; people who successfully manage the transition are poised for emotional and sexual satisfaction (Palacios et al., 2002). Having a healthy attitude to sexuality, as well as maintaining good physical health, will maximize potential for ongoing sexual health in old age (Ginsberg, 2006).

Sexual Response Cycle. Masters and Johnson (1966) developed a four-stage model explaining the human **sexual response cycle**. The model suggested that major similarities exist between men and women. The four stages of the model are excitement, plateau, orgasm, and resolution, and they represent episodes of **vasocongestion** (swelling of tissues) and muscle contractions.

In the **excitement** stage, the heart rate and blood pressure increase, and blood flows into the sexual organs. In women, the breasts enlarge in size, and a reddish flush may be seen over the upper torso. The nipples become more erect. Increased blood flow to the genitalia results in enlargement of the clitoris; engorgement of the labia majora, which flatten and spread outward; and swelling of the labia minora. The upper two-thirds of the vagina enlarge, and the vaginal walls thicken. The

* BOX 26-1 RESEARCH HIGHLIGHT

Gender Issues and Sexual Desire: The Role of Emotional and Relationship Issues

This study assessed the differences between men and women regarding the role of emotional and relationship factors and sexual desire.

Research Focus

Sexual desire is often seen as a precursor to sexual activity, and relationship and emotional factors are not often taken into account. This research is important because sexual desire does not usually occur in a vacuum but rather in the context of the relationship among partnered people.

Research Abstract

Carvalho and Nobre (2010) gave 250 men and 237 women a number of questionnaires that measured emotions, partner adjustment, psychopathology and frequency of sexual desire. These participants were all from the general population and did not disclose any sexual problems prior to the study. Findings indicate that women have greater emotional hurt during sexual activity than men do but men experienced more fear and shame than women. Those with low desire scored lower on the partner adjustment scale as well as experiencing higher levels of disillusion. Those with higher desire experienced greater satisfaction. The researchers concluded that when clinicians work with couples experiencing low desire in one or both, couple adjustment and emotions during sexual activity are important to consider.

Evidence-Informed Practice

- Men and women experience different emotions related to sexual desire.
- Clinicians must consider social and cultural factors when assessing for problems related to sexual desire.
- Both men and women experience greater satisfaction with the relationship when levels of sexual desire are high.

Reference: Carvalho, J., & Nobre, P. (2010). Gender issues and sexual desire: The role of emotional and relationship issues. *Journal of Sexual Medicine*, 7, 2469–2478. doi:1111/j.1743-6109.2009.01689.x.

vaginal walls also secrete a fluid that allows for penile penetration. In men, the penis becomes erect as blood flows into the spongy tissues. The skin of the scrotum thickens, and the testicles swell; the scrotum elevates, and the testicles move in toward the body.

The **plateau** phase is a state of advanced arousal. Blood pressure and heart rate continue to increase, and breathing may become rapid. In women, the lower third of the vagina (at the entry to the vagina) swells. The upper vagina continues to expand, and the uterus moves into an upright position. The labia minora become more engorged with blood and become a darker colour. The clitoris shortens and withdraws below the clitoral hood. The breasts continue to increase in size. In men, the testicles continue to enlarge. The head or glans of the penis changes to a deeper colour.

Orgasm is the phase of significant muscular contractions. During this phase, respiration and heart rates peak, and subjective feelings of intense pleasure radiate through the body. Most of the major muscles in the body contract and may go into spasm. In women, the pelvic muscles contract between 3

and 15 times. The muscles of the anal sphincter and the uterus itself contract. Orgasm in the male occurs in two stages; in the first phase, seminal fluid is forced into the bulb of the penis by contractions of the vas deferens, the two seminal vesicles, the ejaculatory ducts, and the prostate gland. The bladder neck closes off to prevent urine from mixing with the semen. The second stage of orgasm for the man occurs when the muscles around the urethra contract and fluid is propelled along the urethra and out of the urethral meatus. These contractions are accompanied by subjective feelings of intense pleasure.

In the *resolution* phase, vasocongestion diminishes, and the rest of the body returns to its normal state: muscle tension is reduced within minutes, and heart rate, blood pressure, and respiration rate return to normal. During this phase in women, blood flow to the pelvic organs is reduced. The breasts return to their normal size, and flushing of the skin disappears. In men, the penis loses its rigidity, and the testicles and scrotum shrink in size. In men, this phase is followed by a refractory period during which orgasm and ejaculation are physiologically impossible. In young men, the refractory period may last a few minutes, but as men age, this period lasts longer, and older men may not be able to have another orgasm or ejaculation for many hours or even days. Women do not experience a refractory period; they may have multiple orgasms with continued stimulation.

Kaplan (1979) introduced the idea of desire in her description of the human sexual response cycle. Her model comprised three parts: desire, excitement, and orgasm. In Kaplan's model, emotion and cognition, which lead to the subjective feeling of desire, are an important part of sexual response. Excitement and orgasm in this model is as described in Masters and Johnson's (1966) model. Kaplan did not include resolution in her model; she suggested that the cycle has three independent phases. Also, according to this model, it is possible to experience excitement without having experienced desire first.

Basson (2005) more recently described an alternative model of the female sexual response cycle. It relied heavily on psychoemotional processes, as opposed to the more physiological basis of Masters and Johnson's (1966) and Kaplan's (1979) models. In her model, desire (or *libido*) is thought to occur at a variety of points in the sexual response cycle. The female sexual response cycle is conceptualized as a circular rather than linear process, as described in the two previous models. Basson suggested that women rely on different reasons to be receptive to or instigators of sexual activity; rewards such as emotional intimacy, feelings of well-being, and lack of negative feelings resulting from avoiding sex are all factors that may cause a woman to feel desire. With varied motivations for sexual activity, women respond to sexual stimuli from a partner. When the woman receives these stimuli, they are processed psychologically and physically; this may then lead to subjective feelings of arousal and a responsive feeling of desire. Sexual satisfaction is thought to further increase motivation and willingness to be receptive at a future time. Basson reasoned that satisfaction does not necessarily mean orgasm; she suggested that for many women, feelings of closeness and intimacy and the partner's satisfaction may be enough to cause satisfaction for the woman.

Sexual Behaviour

Sexual behaviour typically comprises the broad array of sexual activities people participate in, such as masturbation, hugging, kissing, manual stimulation of a partner, vaginal or anal

penetration, oral-genital stimulation, oral-anal stimulation, sexual excitement while looking at erotica, and telephone or "cyber" sex (Bernhard, 2002; Engender Health, 2004). It is difficult to define "normal" and "abnormal" because wide variation exists between cultures and at different times in society. An inclusive attitude is that whatever people find pleasurable is "normal" as long as it occurs between consenting adults who engage in sexual behaviour by choice, in a safe environment where rules and boundaries are negotiated and respected.

High-Risk Sexual Behaviour. Because body fluids can be transferred between partners, unprotected sex can result in pregnancy or the transmission of STIs. **Safer sex** refers to sexual activities that present minimal or reduced risk for disease transmission or unintended pregnancy. Unsafe sex refers to activities through which risk for infection, unintended pregnancy, or injury is decreased. Unsafe sex includes anal-penile or vaginal-penile intercourse without a condom (Society for Human Sexuality, 2004). Without the use of barriers such as condoms or latex dental dams, penile-anal intercourse is probably the riskiest activity, followed by penile-vaginal intercourse, oral-anal sex, and oral-genital sex.

The dynamics of sexual risk taking are not fully understood, but numerous studies have revealed that drug and alcohol use are highly correlated with sexual abuse and unsafe sex (Keller et al., 1996; Kenney et al., 1998). Adolescents, especially, tend to have a sense of being invincible, believing that unwanted pregnancy, STIs, and other negative outcomes of sexual behaviour are not likely to happen to them (Ross et al., 2000).

Sexually Transmitted Infections

A number of STIs are of concern to public health officials and health care providers. In Canada, health officials report increases in all of the infections that, by law, must be reported, including chlamydia, gonorrhea, and syphilis (Public Health Agency of Canada, 2004).

A major problem in dealing with STIs is finding and treating the people who have them. Because symptoms may be absent or go unnoticed, some people may not even know that they are infected. Sexual behaviour may include the whole body rather than just the genitalia; therefore, many parts of the body are potential sites for an STI. The mouth, tongue, and throat are commonly used for sexual pleasure. The vagina, perineum, anus, and rectum are also frequently included in sexual activity. Furthermore, any contact with another person's body fluids near an open lesion on the skin, anus, or genitalia can result in transmission of an STI.

Sometimes people do not seek treatment because they are embarrassed to discuss sexual symptoms or concerns. They may also hesitate to talk about their sexual behaviour if they believe that it is not "normal." This hesitation to seek help often hinders the detection of an STI.

Syphilis. Syphilis, a bacterial infection, can be transmitted through oral, vaginal-penile, or anal sex with an infected person. A pregnant woman with syphilis can pass it on to her baby, which can lead to birth defects or death in the baby. Syphilis also can be transmitted through injection drug use or through broken skin or sores, although transmission by these routes is not common. Syphilis can be diagnosed with a simple blood test and is easily treated with antibiotics. If it is not treated, syphilis can affect the brain, blood vessels, heart, and bones. It can also cause death. Males older than 30 years account for the majority of syphilis cases in Canada (Public

Health Agency of Canada, 2004), and local outbreaks are reported periodically across the country.

Chlamydia. The most common of all bacterial STIs, chlamydial infection may cause an abnormal genital discharge and burning with urination; however, it is often asymptomatic. It is treated by an antibiotic.

Chlamydia produces many serious complications in women. If undetected and thus untreated, it can progress to pelvic inflammatory disease in women, a very painful and sometimes debilitating disease that is linked to infertility. An untreated chlamydial infection may cause scarring of the uterine tubes, which increases the risk for ectopic pregnancy and infertility. Research findings suggest that chlamydial infection is also a risk factor for the transmission of the human immune deficiency virus (HIV), and it could be a risk factor for cervical cancer (Anttila et al., 2001). It is estimated that fewer than 10% of chlamydial infections are diagnosed and treated (Public Health Agency of Canada, 2004). Women, particularly those younger than 30 years, are most affected; women account for two-thirds of all reported chlamydia cases in Canada (Public Health Agency of Canada, 2004).

Gonorrhea. Gonorrhea is easily transmitted during vaginal-penile intercourse, anal-penile intercourse, and oral sex (Birley et al., 2002). It can affect the penis, cervix, rectum or anus, throat, and eyes. Pain during sex or during urination, or unusual discharge, may be indications of a gonorrheal infection. Gonorrhea must be treated with antibiotics. If left untreated, it may cause serious health problems, including infertility. It can also cause blood, joint, and eye infections in a baby born to an infected woman (Planned Parenthood Federation of America, 2008b). Gonorrhea is the second most commonly reported bacterial STI in Canada, and its prevalence is also increasing. Men aged 20 to 29 years are the most affected age group in Canada. Of the cases among women, 70% occur in those aged 15 to 24 years. Antibiotic-resistant strains of the bacterium are becoming a problem in some regions of Canada (Public Health Agency of Canada, 2004).

Human Papillomavirus. Human papillomavirus (HPV) is not required to be reported, although it is a very serious STI. It is strongly linked with cervical cancer (Division of STD Prevention and Control, 2000). It may be manifested as external genital warts that occur on the penis, scrotum, perineum, vulva, and perianal area; they usually appear as small, hard, painless bumps. These warts can also occur in the vagina, on the cervix, inside the urethra, and inside the anus (Beutner et al., 1998). If untreated, they may grow and develop a fleshy, cauliflowerlike appearance. Because they are caused by a virus, genital warts cannot be cured. They are treated with a topical drug (applied to the skin), by freezing, or, if they recur, with injections of medication. If the warts are very large, they can be removed surgically. A preventive vaccine for HPV has been approved; it offers protection against four HPV types, which together cause 70% of cervical cancers and 90% of genital warts (Centers for Disease Control and Prevention, 2008). The recommendation is that girls and women between the ages of 9 and 26 be offered this vaccine; it is important that the vaccine be given before the initiation of sexual activity. Women who are sexually active may receive the vaccine but, because they may have already been exposed to some strains of HPV, are less likely to benefit. The HPV vaccine has also been shown to be effective in men (Giuliano et al., 2011), and Health Canada has approved its use in men aged 9 to 26 years.

HPV is also associated with development of oral cancer, and the incidence of this cancer among young adults aged 20

to 39 is rising. HPV subtypes 16 and 18 are most often associated with oral cancer, and the virus is readily spread through mucosal contact (Kreimer et al., 2005). This connection is not widely known among the public. Physicians and dentists may not ask about oral sex, and their index of suspicion for oral cancer in young adults may be low (Brondani et al., 2010).

Genital Herpes. Genital herpes, caused by the herpes simplex virus, is the most common manifestation of genital ulceration and is often transmitted by people who have no visible or symptomatic lesions (Public Health Agency of Canada, 2004). Genital herpes can cause extensive ulceration (painful blisters or open sores), with severe pain. Without treatment, episodes can last for three or more weeks, and many people with herpes have recurrent episodes. At present, the viral infection is incurable; antiviral drugs can only control the symptoms and suppress transmission.

Human Immunodeficiency Virus Infection. HIV is the virus that causes acquired immune deficiency syndrome (AIDS). Essentially, HIV destroys the body's ability to defend against infection. Many people do not have symptoms when they first are infected with HIV, although some may have a flulike illness within one to two weeks after exposure. More persistent or severe symptoms may not appear for 10 years or more after infection. During the asymptomatic period, however, the virus is actively multiplying, infecting, and killing cells of the immune system. As the immune system weakens, various complications occur (National Institute of Allergy and Infectious Diseases, 2003).

AIDS represents the most advanced stages of HIV infection. The syndrome can result in many infections that do not usually affect healthy people. In people with AIDS, these infections are often severe and sometimes fatal. People with AIDS are particularly prone to developing cancers, especially those caused by viruses (such as Kaposi's sarcoma or cervical cancer) and those of the immune system (such as lymphomas).

In an infected person, HIV is present in the majority of body fluids. For transmission to occur, therefore, some exchange of body fluid, particularly blood, must occur. Primary routes of transmission include contaminated intravenous needles, unprotected sexual activity (anal intercourse, vaginal intercourse, and oral-genital sex), and transfusion of blood and blood products. HIV can also be spread from infected mothers to their babies during pregnancy, at birth, or during breastfeeding. HIV has not been proved to be transmitted through sweat, tears, saliva, or urine.

By the end of 2004, it was estimated that 57,674 positive results of HIV tests were confirmed in Canada and reported to the Public Health Agency of Canada. Rates of infection are highest in men who have sex with men, in Aboriginal people, in injection drug users, and in immigrants from countries where HIV is endemic (Centre for Infectious Disease Prevention and Control, 2003). Women account for 25% of all HIV infections in Canada (Public Health Agency of Canada, 2004). Many Canadians who are currently infected with HIV do not know that they are.

Although medications enable individuals with HIV to stay healthy longer, and although they help prevent the transmission of HIV from a pregnant woman to her newborn, medications cannot cure the disease (McIlhaney, 2000).

Prevention of Sexually Transmitted Infections. People most likely to be infected with an STI are those who have unprotected sex. Exposure to multiple partners or to a sexual partner who has many partners increases the risk of acquiring an STI. Injection drug users are also a high-risk

group because they share blood by sharing needles. Primary prevention of STIs starts with changing the sexual behaviour that heightens the risk for infection. Health promotion must be targeted toward high-risk groups and must emphasize education and counselling regarding safer sexual behaviour. STIs often occur together, and screening is usually performed for all STIs at the same time.

Safer Sex. *Safer sex* refers to the sexual practices and behaviour that reduce the risk of contracting and transmitting STIs, especially HIV. When a partner is infected or when the infection status of a partner is not known, it is crucial to practise safer sex. For vaginal-penile and penile-anal intercourse, partners should use condoms. Safer sex practices are also necessary for oral sex; if one of the partners is a woman, a thin piece of rubber, a latex dental dam, a female condom, or an unlubricated male condom cut open to form a flat piece of latex should be placed between the other partner's mouth and the woman's vulva before any oral contact is made. Male partners should cover their penis with an unlubricated condom before any oral contact is made (Engender Health, 2004).

Using Condoms. Condoms were originally sold to promote birth control. However, when used correctly, they also provide protection against STIs. A condom acts as a barrier to keep blood, semen, and vaginal fluids from passing from one person to another. In Canada, condoms are free at many public health clinics and readily available from drugstores and supermarkets. Condoms can be made from latex, polyurethane, or natural membranes such as sheepskin or lambskin. Latex and polyurethane condoms reduce the risk of most STIs (including HIV) and help protect against pregnancy. Natural membrane condoms do not protect against STIs because some bacteria and viruses can pass through small pores in the material (Centre for Infectious Disease Prevention and Control, 2002).

A female condom is a strong, soft, clear sheath made of polyurethane with two rings at either end. It is placed inside the vagina before sex and protects against pregnancy and STIs (including HIV). When placed correctly, one end covers the cervix and the other end covers part of the external genitalia (Planned Parenthood Federation of America, 2008a).

Contraception

Contraception is a crucial facet of sexual health to avoid unwanted pregnancies. Some forms of contraception require a health care provider's intervention: hormonal contraceptives (e.g., birth control pills or patch, injectable contraceptives), intrauterine devices (IUDs), the diaphragm, the vaginal contraceptive ring, and the cervical cap. Surgical procedures that provide permanent contraception are also available to men (vasectomy) and women (tubal ligation). Other forms of contraception do not require a prescription or intervention from a health care provider: condoms, contraceptive sponges, vaginal spermicides, and fertility awareness methods (i.e., timing of intercourse in relation to the menstrual cycle). Table 26-1 summarizes some of the contraceptive choices available.

Effective contraception involves factors relating to the sexually active couple, the method of contraception, the couple's understanding of the contraceptive method, the consistency of contraceptive use, and the compliance with the requirements of the chosen method. Personal characteristics that have been identified as positively influencing contraceptive use include motivation to avoid unplanned pregnancy, ability to plan, comfort with sexuality, and previous contraceptive use (Running & Berndt, 2003). Cultural and religious background

may permit certain practices and prohibit others. For example, the teachings of the Roman Catholic Church prohibit the use of contraception except for the fertility awareness method.

Emergency Contraception. Emergency contraception pills (ECPs, or "morning after" pills) can prevent a woman from becoming pregnant after unprotected vaginal-penile sex. ECPs are most effective up to 72 hours after intercourse, and the sooner they are taken, the more effective they are (Public Health Agency of Canada, 2006). They are recommended to women when contraception was not used, when a condom broke, when a diaphragm slipped, when a birth control injection was given over one week late, when two or more birth control pills were missed, or in cases of rape. When hormonal ECPs are taken within 72 hours (three days) after unprotected sex, the risk of getting pregnant is reduced by approximately 75%. ECPs have been shown to be effective up to five days after intercourse.

Women can obtain ECPs from family physicians, nurse practitioners and midwives, hospital emergency rooms, or walk-in clinics. As of 2005, Canadian pharmacists may dispense ECPs without a physician's prescription; however, pharmacists have the right to refuse to do so if it conflicts with their personal beliefs. ECPs are available for free or at minimum cost at many university health services, sexual health clinics, birth control clinics, Planned Parenthood clinics, and women's health clinics. Adolescent girls do not require parental consent to obtain ECPs, and no medical examination is required.

Abortion

Since 1988, Canada has been one of the few countries without any legal restrictions on abortion. Canada has no requirements for waiting periods, parental or spousal consent, gestational limits, or restrictions on types of elective abortion. Abortion is also a safe procedure, especially if performed within the first trimester of pregnancy. Some provinces fully fund all elective abortions; others fund only those performed in hospitals. However, access to abortion services is often a problem for women living outside major cities. Two-thirds of abortions are performed in hospitals; the remainder are performed in abortion clinics and health centres. However, only 18% of hospitals across the nation provide abortions (Canadian Abortion Rights Action League, 2003). In Prince Edward Island and Nunavut, no hospitals provide abortions.

Abortion continues to be a hotly debated issue. Women and their partners faced with an unwanted pregnancy may consider an elective abortion. As a nurse, you can provide an environment in which the issue of abortion can be discussed openly and various options with an unwanted pregnancy can be explored. You should discuss religious, social, and personal issues in a nonjudgemental manner with patients. Reasons for choosing an elective abortion vary and may include terminating an unwanted pregnancy or aborting a fetus known to have abnormalities. When abortion is chosen as a way of dealing with an unwanted pregnancy, the woman, and often her partner, may experience a sense of loss, grief, or guilt, or a combination of these. Guilt may surface immediately, or it may be more covert and manifest as sexual dysfunction.

Health care providers must reflect on their own personal values related to abortion. The health care provider is entitled to personal views and should not be forced to participate in counselling or procedures contrary to beliefs and values. Nurses should choose specialties or places of employment in which their personal values are not compromised and the health care that a patient needs is not jeopardized.

► TABLE 26-1 Available Contraceptives

Type	Effectiveness	Description
Male condom	86%–97%	A thin, skin-tight sheath placed on an erect penis to stop sperm from entering a partner's body. Water-based lubricants can make them more comfortable, increase sensation, and reduce the risk of breakage.
Female condom	79%–85%	A lubricated pouch that is placed in the vagina before penile insertion; it stops sperm from entering the woman's body. It may break or slip, and some women may have difficulty placing it correctly.
Birth control pills	98%–99%	Pills taken every day that contain a low dose of hormones (estrogen and progestin or progestin alone). The ovaries are prevented from releasing an egg for fertilization, eggs are prevented from implanting, and the mucus around the cervix is thickened, which makes entry of the sperm more difficult. They are available only by prescription.
Cervical cap	80%–91%	A small, flexible cup that is inserted into the vagina before penile insertion. It covers the cervix and prevents sperm from entering the uterus. The caps are available in different sizes; proper fitting by a trained health care provider is required.
Intrauterine device (IUD)	99%	A small piece of plastic or copper that is inserted into the uterus by a physician. Sperm is prevented from fertilizing an egg, or, if an egg is fertilized, the egg is prevented from implanting in the uterus. Some IUDs also release hormones to prevent pregnancy. IUDs can stay in place for 1–8 years.
Birth control patch	99.2%–99.4%	A thin, 2 cm × 2 cm patch that can be worn on the lower abdomen, buttock, upper arm, or upper torso. The patch is applied once a week for 3 consecutive weeks; the fourth week is patch free. The mechanism of action is the same as that of oral contraceptives.
Injectable contraceptive	99.70%	Progestin is injected into a woman's arm or buttocks once every 12 weeks. The hormone prevents the ovaries from releasing eggs. A physician or nurse administers the injections.
Vaginal contraceptive ring	98.3%–99.4%	A soft, flexible, transparent ring that is self-inserted into the vagina and delivers hormones over 3 weeks, after which time the ring is removed for 1 week. A new ring is then inserted.
Contraceptive sponge	80%–91%	A soft sponge that is filled with spermicide and placed in the vagina before vaginal-penile intercourse. It is effective for 24 hours after placement. The sponge must be kept in place for 6 hours after intercourse.
Vaginal spermicides	78%–90%	Gels, films, and suppositories, which contain a spermicidal agent, that are inserted into the vagina before vaginal-penile intercourse. The agent kills sperm and acts as a physical barrier to prevent any surviving sperm cells from entering the cervix. This approach may be used by women who are at low risk for STIs and whose partners are at low risk.
Fertility awareness method	90%–98%	A woman can monitor her fertility patterns and know, on the basis of daily observations of body temperature and cervical mucus, when she is most likely and least likely to conceive. She must abstain from vaginal-penile intercourse when she is most likely to conceive. This method can also be used to achieve pregnancy.
Tubal ligation	99.50%	A surgical procedure in which a woman's uterine tubes are tied into a loop and then cut. This procedure is performed with the woman under general anaesthesia, and its effects should be considered permanent.
Vasectomy	99.90%	A minor surgical procedure for men in which the vas deferens that carry the sperm are cut, "tied," cauterized, or otherwise interrupted. The semen no longer contains sperm after the tubes are cut, and conception cannot occur. The procedure can be performed in a physician's office with a local anaesthetic. The results of this procedure should be considered permanent.

Nursing Knowledge Base

In planning to help patients address sexual needs, you should use critical thinking skills and basic nursing knowledge. You may draw from the following areas of nursing knowledge: sociocultural dimensions of sexuality; how to discuss sexual issues; alterations in sexual health (infertility, sexual abuse, sexual dysfunction); and conditions that create sexual health concerns (pregnancy, surgery, illness, disability).

Sociocultural Dimensions of Sexuality

Sexuality is influenced by cultural rules and norms that determine which behaviour is acceptable within the culture. Society

plays a powerful role in shaping sexual values and attitudes and in supporting specific expression of sexuality in its members. Each cultural and social group has its own set of rules and norms that guide the behaviour of its members. These rules become an integral part of an individual's thinking and underlie sexual behaviour; they include, for example, how people find partners, their choices of partners, how they relate to one another, how often they have sex, and what they do when they have sex.

It is widely suggested that nurses include information about sexual health and the implications for sexuality when they care for patients. Nurses should also routinely ask patients whether they have any sexual concerns related to their

condition or treatments (Albaugh & Kellog-Spadt, 2003). However, this question is frequently omitted, and a valuable opportunity to be proactive and holistic in the care provided is thus missed (Haboubi & Lincoln, 2003). You may feel that asking about sexuality is an invasion of patients' privacy (Bartlik et al., 2005), or you may think that gender is a barrier (Burd et al., 2006). Nurses appear to be more likely to wait for the patient to initiate the discussion than to assess this routinely (Guthrie, 1999). You may think that the patient does not expect you to ask questions about this (Magnan et al., 2005), or you may believe that it is the physician's responsibility (Herson et al., 1999). As a result, sexual problems may not be recognized and thus may be ignored. Some nurses may presume that because of the seriousness of the patient's disease or because of the patient's stage of life, sexuality is not an important issue (Huang, 1999); this presumption can have consequences such as lack of education for the patient.

Discussing Sexual Issues

Sexuality is a significant part of each person's being; however, sexual assessment and interventions are not always included in health care. The area of sexuality can be emotionally charged for nurses as well as for patients. Discomfort with talking about sexual issues, lack of information, and differences between a patient's values and the nurse's values may prevent the nurse from discussing issues of sexuality with patients. The most valuable tool that you can develop for providing care in areas of sexuality is effective, nonjudgemental communication. If you have difficulty discussing topics related to sexuality, you should understand why, and you should develop a plan for addressing your discomfort.

Discussing matters of a sexual nature can also be embarrassing for patients. Often, patients do not mention sexual health issues; they may worry about looking stupid, using incorrect words, or being offensive, or they may simply have no way of describing their concerns. It is crucial that you be comfortable in asking questions about sexuality and in responding to issues that arise from such questioning. By using a perceptive and educated approach to talking about sexuality, you can offer the support that many patients require.

Effective communication about sexuality requires caring, sensitivity, tact, compassion, the use of appropriate language, and nondiscriminatory attitudes. When talking with patients about sexuality, it is important not to have preconceived notions about their sexual identity or activity. Homosexual and bisexual people may not receive adequate health care if health care providers assume heterosexual sexual orientation and fail to obtain complete sexual histories. Older adults' sexual health may also be overlooked if health care providers stereotype these patients as asexual.

Alterations in Sexual Health

Infertility. Infertility is the inability of a couple to conceive after one year of unprotected intercourse. A couple who wants to conceive and cannot may experience a sense of failure and feel that their bodies are somehow defective. Infertility may become an emotionally draining facet of their lives, and the treatments also affect their sexual lives and relationship. With advances in reproductive technology, infertile couples face many choices, some of which involve challenges to their religious and ethical values and may cause financial strain.

Choices for the infertile couple include medical assistance with fertilization, adoption, or exploring the possibility of

remaining childless. Infertility support groups can provide couples with emotional and educational help. For example, the Infertility Awareness Association of Canada, a national support group for couples with infertility, can be helpful in offering educational resources and assistance.

Sexual Abuse. Sexual abuse is a widespread health problem. Abuse crosses all gender, socioeconomic, age, and ethnic groups. Most often, this abuse is perpetrated by a former intimate partner or by a family member. Sexual abuse has far-ranging effects on physical and psychological functioning (Dickinson et al., 1999). Increasingly, sexual abuse is occurring through the Internet: sexual predators recruit victims on social networking sites and then arrange to meet the victims, after which the abuse begins.

Evidence of sexual abuse in children may be uncovered during history taking or physical examination (see Chapter 31). Symptoms that should raise suspicion of sexual abuse include a child showing an early, exaggerated awareness of sex or exhibiting seductive behaviour toward adults; swelling or bruising of the external genitalia, anus, breasts, or buttocks; lacerations of or a foreign substance in the vagina or anus; and an STI in a child younger than 15 years. In Canada, nurses are required by law to report suspected child abuse to child protection authorities. Signs and symptoms of sexual abuse are listed in Box 26-2.

When sexual abuse is recognized, support needs to be mobilized for the victim and the family. All family members may require therapy in situations of incest to promote healthy interactions and relationships. Rape victims may need to come to terms with the crisis before feeling comfortable with intimate expressions of affection. The victim's partner may need

► BOX 26-2

Signs and Symptoms That May Indicate Current or Previous Sexual Abuse

- Irritation or injury (such as cuts and bruises or scarring) of the thighs, perineum, or breasts
- Trauma to mouth and throat, including petechiae of the oral cavity
- Oral STIs
- Intense fear of bathing or perineal care
- Vaginal discharge, genital odour, and painful urination
- Difficulty walking or sitting
- Avoidance of casual touching
- Sleep pattern disturbances
- Nightmares
- Depression
- Anxiety
- Decreased self-esteem
- Difficulties with intimate relationships
- Substance abuse
- Frequent visits to health care providers
- Headaches
- Gastrointestinal problems
- Eating disorders
- Abdominal pain
- Vaginal pain
- Dysmenorrhea

► TABLE 26-2 Types of Sexual Dysfunction

Category	Type*	Definition
Sexual desire disorders	Hypoactive sexual desire disorder	Persistent or recurrent deficiency or absence of sexual fantasies and desire for sexual activity
	Sexual aversion disorder	Persistent or recurrent extreme aversion to, and avoidance of, all or almost all genital sexual contact with a sexual partner
Sexual arousal disorders	Female sexual arousal disorder	Failure in a woman to attain or maintain the lubrication-swelling response or to experience a subjective sense of sexual excitement and pleasure during sexual activity
Male erectile dysfunction		Persistent or recurrent inability to attain an adequate erection or to maintain an adequate erection until completion of the sexual activity
Orgasmic disorders	Female orgasmic disorder (anorgasmia)	The recurrent and persistent inhibition of the female orgasm, as manifested by the absence or delay of orgasm after a period of sexual excitement the clinician judges adequate in intensity and duration to produce such a response
	Male orgasmic disorder (retarded ejaculation)	Persistent or recurrent delay in, or absence of, orgasm after a normal sexual excitement phase during sexual activity that the clinician, taking into account the man's age, judges to be adequate in focus, intensity, and duration
	Male orgasmic disorder (premature ejaculation)	Persistent or recurrent ejaculation with minimal sexual stimulation before, upon, or shortly after penetration and before the man wishes it
Sexual pain disorders	Dyspareunia	Recurrent or persistent genital pain in either a man or a woman before, during, or after sexual intercourse that is not associated with vaginismus or with lack of lubrication
	Vaginismus	An involuntary constriction of the outer third of the vagina that prevents penile insertion and intercourse
Sexual dysfunction resulting from drug use or diseases		Sexual dysfunction judged to be caused by the direct physiological effects of a general medical condition or use of a substance

*According to American Psychiatric Association. (In press). *Diagnostic and statistical manual of mental disorders* (5th ed.). Washington, DC: Author.

support in understanding this process and ways to assist the victim. Children who have been sexually abused need to understand that they are not at fault for the incident. The parents must understand that their response is critical to how the child reacts and adapts. You may come in contact with patients confronting these stressors. You are in an ideal position to assess occurrences of sexual violence and to educate individuals about community services. You should be aware of resources for referral and support in the community.

Sexual Dysfunction. Sexual dysfunction is a common, complex problem that arises because of biological, psychological, and interpersonal factors (Table 26-2). Sexual problems and dysfunction are often associated with health problems such as heart disease, diabetes, cancer, and mental illness. It is not known how many people experience sexual dysfunction, and it is most probably a minority who seek help. Researchers estimate that between 10% and 52% of men and 25% and 63% of women have sexual problems, although the prevalence of sexual dysfunctions that meet the diagnostic criteria of the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association, in press) is lower (Heiman, 2002). For most people, sexual dysfunction is perplexing and emotionally disturbing, and it adversely affects their primary relationship.

Sexual dysfunction can usually be treated with either medical interventions (mostly pharmacological) or psychological interventions (e.g., cognitive and behavioural methods). The aim is typically to achieve changes in physical (genital response, orgasms) or subjective (greater desire, ease of orgasm) responses (Heiman, 2002).

Sexual Dysfunction in Women. Loss of sexual desire is the most common reason that women seek help for sexual

dysfunction (Butcher, 1999a). Despite considerable research, sexual desire is poorly understood. Medical conditions (including depression), stress, and fatigue affect sexual desire. Painful intercourse is another common sexual dysfunction in women. Recurring sexual pain can produce a cycle in which trepidation because of previous pain leads to avoidance of the sexual activity that produced it, which leads to lack of arousal, failure to achieve orgasm, and loss of sexual desire (Butcher, 1999b). This cycle can evolve to avoidance of sexual activity altogether.

Sexual Dysfunction in Men. One of the most common types of sexual dysfunction for men is erectile dysfunction. It is estimated that about 27% of sexually active Canadian men experience erectile dysfunction, which is the repeated inability to achieve or maintain an erection (Auld & Brock, 2002). Erectile dysfunction can be caused by any health problem, including heart disease, hypertension (or its treatment), diseases of the prostate, diabetes mellitus, multiple sclerosis, and depression. Indeed, erectile dysfunction might be a warning sign of undiagnosed cardiovascular disease.

Patients With Particular Sexual Health Concerns

Pregnant and Postpartum Women. Female sexual interest tends to fluctuate during pregnancy; it increases during the second trimester and often decreases during the first and third trimesters. The decrease in libido during the first trimester may be caused by nausea, fatigue, and breast tenderness. During the second trimester, blood flow to the pelvic area is increased to supply the placenta, and sexual enjoyment and libido accordingly increase. During the third trimester, increased abdominal size may make finding a comfortable position difficult.

The most prevalent sexual problem during pregnancy is fear of harming the fetus. However, pregnancy and birth complications are not associated with sexual intercourse (von Sydow, 1999). If women have a history of miscarriages or premature labour, they may be advised to avoid sexual intercourse during the later months of pregnancy. Other restrictions such as no orgasms or no sexual arousal may be necessary to protect high-risk pregnancies (Mayo Foundation for Medical Education and Research, 2004).

Patients Recovering From Surgery. Surgeries that result in disfigurement, especially of the face, breasts, genitalia, and reproductive organs, frequently have harmful effects on a patient's self-image and sexuality (de Marquiegui & Huish, 1999). The effects of surgery, whether temporary or permanent, are often not fully anticipated and may not be fully manifested until after discharge from the hospital. Patients' partners might also have adjustments to make and may find it difficult to resume sexual activity. Coping with anxiety, fear, or depression about the surgery is essential. You need to support patients to discuss their concerns, especially sexual anxieties, because problems can become deep-rooted, complicated, and more difficult to resolve over time (de Marquiegui & Huish, 1999). Patients who have had ileostomies, colostomies, or urostomies are particularly concerned about possible loss of control, unpleasant smells or sounds, seepage or broken bags, and their partners' responses (see Chapter 44). Perioperative counselling and support are essential for these patients.

Patients With Illness or Disabilities. Illness and disability often affect sexual health. During periods of illness, individuals may experience major physical changes, the effects of drugs or treatments, the emotional stress of a prognosis, concern about future functioning, and separation from significant others. Situational stressors could include a heart attack (myocardial infarction); cancer diagnosis and treatment; or chronic disease such as diabetes, multiple sclerosis, or Parkinson's disease. You should not assume, because of a patient's age or severity of prognosis, that sexual functioning is not a concern. In some instances, patients may wrongly believe that their condition prohibits sexual activity, or they may need some guidance to promote satisfactory sexual functioning (Nusbaum et al., 2003).

Many myths are prevalent about people with a disability, including the idea that they are asexual or somehow different. Without doubt, long-term disability can have profound effects on a person's sense of sexuality and sexual function. Congenital or birth impairments commonly affect sexual development; for example, the resulting lack of privacy and independence may mean that people with disabilities miss out on typical sexual experiences (Glass & Soni, 1999). Acquired disabilities may have different implications: impairments sustained in youth may bring about low social and sexual confidence, and people who sustain disabilities as adults may be far more aware of what they have lost. It is important that health care providers validate a disabled person's sexuality. You can do this by sensitively initiating conversations about sexual function and safer sex practices.

Critical Thinking

Successful critical thinking requires synthesis of knowledge, experience, information gathered from patients, critical thinking qualities, and intellectual and professional standards. Clinical judgement requires you to anticipate the information

Figure 26-3 Critical thinking model for sexuality assessment. OB-GYN, Obstetrical-gynecological; STIs, sexually transmitted infections.

necessary, analyze the data, and make appropriate decisions regarding patient care. Figure 26-3 depicts numerous critical thinking elements, as well as patient assessment data, that contribute to appropriate nursing diagnoses.

In the case of sexuality, you integrate knowledge from nursing and other disciplines. You must have a good understanding, for example, of the human sexual response cycle, safer sex practices, and the taxonomy of sexual problems, as well as solutions to these, to anticipate how to assess a patient and then how to interpret findings. Previous experience in caring for patients whose sexuality becomes threatened helps you approach the next patient in a more reflective and helpful way. Patients may have customs and values different from yours. Professional standards call for you to respect each patient as an individual.

Sexuality and the Nursing Process

A person's sexuality has physical, psychological, social, and cultural elements. You must assess all relevant elements to determine a patient's sexual well-being. You should build a sound knowledge base and be willing to explore personal issues regarding sexuality. The nursing role in addressing sexual concerns can range from ongoing assessment to providing information to counselling to referral.

❖ Assessment

Factors Affecting Sexuality

In gathering a sexual history, you should consider physical, functional, relationship, lifestyle, and self-esteem factors that may influence sexual functioning.

Sexual Health History

When taking a health history, you should include a few questions related to sexual functioning to determine whether the patient has any sexual concerns. You can incorporate these questions in the review of systems and address them in a routine, matter-of-fact manner. It is important to ask these questions once you have established rapport with the patient; the sexual history is usually taken at the end of the general history. You need to understand the reasons for the questions and be able to provide these reasons to the patient on request. An opening statement such as "Sex is an important part of life and can be affected by our health status. To better understand your health, it is useful to know ..." is a possible introduction to these questions. Other questions for adults might include:

- How do you feel about the sexual aspects of your life?
- Have you noticed any changes in the way you feel about yourself (as a man, woman, husband, or wife)?
- How has your illness, medication, or surgery affected your sex life?
- It is not unusual for people with your condition to be experiencing some sexual changes. Have you noticed any changes, or do you have any concerns?

Conducting a sexual assessment of children and adolescents provides special challenges for health care providers. Common challenges include issues of language, of promoting normal development while not minimizing problems, and of screening for sexual concerns while not unduly alarming children. In addition, the sexual counselling of minors raises ethical and legal issues regarding the patient's rights to health care and education, on the one hand, and the parents' or guardian's right to supervise information, on the other. Use of an open, positive, interested disposition when introducing sexual questions is helpful. It is also helpful to inform parents that you are going to be discussing this in private with their child or teenager and that this is a normal part of the nursing assessment.

When caring for older adults, nurses may adjust their assessment approach. When gathering a sexual history, it is important to keep in mind that the older adult may have difficulty discussing intimate details with health care providers because of cultural and social norms for their age group. You have a responsibility to help maintain healthy sexuality of older adults by offering the opportunity to discuss any concerns or to seek information. Often, asking questions on the topic of sexuality in a comfortable, relaxed manner facilitates older adults' discussion of their sexual needs.

Because of the prevalence of domestic violence and sexual abuse, questions relating to abusive relationships can be important. Questions that address domestic violence or abuse should be addressed to the patient in private. A question such as "Are you in a relationship in which someone is hurting you?" may encourage a patient to reveal current or previous abuse. An additional question such as "Has anyone ever forced you to have sex that you did not wish to participate in?" may more specifically encourage the patient to discuss concerns. Recognizing both subjective and objective signs and symptoms of abuse can aid in recognition of this too-common problem (see Box 26-2). If a person identifies sex abuse as a current or past problem, appropriate referrals need to be made with the patient's permission.

While you document the sexual history of a patient, it is also helpful to explore the patient's use of contraceptives and safer sex practices as appropriate. Adolescents may respond to a comment that reassures them that having questions related to sexuality is normal. A lead-in could be "Many teenagers have questions about whether their bodies are developing at the right rate. Do you have any questions about sex or your body?"

Some individuals are too embarrassed or do not know how to ask questions about sexuality. If a patient makes a sexual joke or expresses concern about relations with his or her partner, he or she may have questions. Observing for and listening to concerns about sexuality takes practice. With experience, you develop skill in clarifying and paraphrasing to help patients express sexual concerns. By including sexuality in the health history, you acknowledge that sexuality is an important part of health and create an opportunity for the patient to discuss sexual concerns.

Physical Assessment

The physical examination is important in evaluating the cause of sexual concerns or problems; however, this is beyond the scope of the generalist nurse and more appropriate for the advanced practice nurse or physician. Talking about sexuality at the time of the genital examination is not appropriate and can be misconstrued by the patient in addition to making him or her feel uncomfortable. Discussions about sexuality are best held when the patient is fully clothed and sitting comfortably in a private room.

Patient Expectations

As in the case of any patient assessment, it is important to understand the patient's expectations regarding his or her care. Questions such as "What would you like to have happen in regard to [expressed concern]?" and "What initial steps might you take?" can help the person identify desired outcomes. It is important for the nurse to set aside personal views and not assume what a patient's expectations might be.

❖ Nursing Diagnosis

After completing an assessment and applying critical thought to the diagnostic process (Box 26-3), you select diagnoses applicable to the patient's needs. Possible nursing diagnoses related to sexual functioning (NANDA International, 2009) are:

- *Anxiety*
- *Ineffective coping*
- *Interrupted family processes*
- *Deficient knowledge (about contraception or STIs or both)*

BOX 26-3 NURSING DIAGNOSTIC PROCESS

Assessment Activities

Observe readiness to discuss sexual concerns through verbalization (e.g., "When can I return to life as normal?" or "There goes my love life") or behaviour (e.g., exhibitionism).

Ask patient and spouse about previous level and method of sexual expression (e.g., frequency, initiator).

Observe for affectionate behaviour (e.g., touching, hand holding, kissing).

In privacy, ask spouse about perceptions of patient's recovery and return to full functioning.

Observe for anxiety (e.g., hand wringing).

Defining Characteristics

Patient verbalizes concern that sexual activity may cause another myocardial infarction or death.

Patient's spouse exhibits reluctance to touch patient.

Spouse verbalizes concern that patient will need continuous care, attention, and protection.

Patient maintains eye contact, shifts position frequently.

Nursing Diagnosis

Ineffective sexuality patterns related to fear of recurrent myocardial infarction or death during intercourse.

- Sexual dysfunction
- Ineffective sexuality patterns
- Social isolation
- Risk for other-directed violence
- Risk for self-directed violence

Clues that may signal risk or an actual nursing diagnosis related to sexuality include a history of surgery involving the reproductive organs, changes in appearance, past or current physical or sexual abuse, chronic illness, and developmental milestones such as puberty or menopause. Before making nursing diagnoses related to sexual dysfunction, you must first assess anatomical, physiological, sociocultural, and situational issues thoroughly.

When making a nursing diagnosis in regard to sexuality, you must clarify with the patient that the defining characteristics do in fact exist and that the patient perceives a problem with regard to sexuality. Determining the etiological or contributing factors is important in order to focus effective planning and to select appropriate nursing interventions. For example, the nursing interventions appropriate for the nursing diagnosis *chronic low self-esteem* would be different from those

Figure 26-4 Critical thinking model for sexuality planning. HIV, Human immunodeficiency virus; PLISSIT, permission giving, limited information, specific suggestions, and intensive therapy; STI, sexually transmitted infection.

appropriate for other etiological factors. For *self-esteem disturbance related to chronic, recurring herpes infection*, the appropriate interventions include counselling and education on how to maintain safer sexual practices. In contrast, *self-esteem disturbance related to sexual abuse* would necessitate counselling and referral to community resources (e.g., crisis services or sexual abuse support group).

❖Planning

Goals and Outcomes

During planning, you again synthesize information from multiple resources (Figure 26-4). You use critical thinking skills to integrate professional standards and knowledge about the patient's sexuality into the care plan. It is especially important to maintain a patient's dignity and identity when you develop the care plan. For example, convey respect for a gay patient by including the help of a gay partner in the plan to the degree that the partner can assist the patient in maintaining his or her identity and dignity.

You develop an individualized care plan for each nursing diagnosis (Box 26-4). Together, you and the patient set realistic goals for care. Expected outcomes must be individualized and

► BOX 26-4 NURSING CARE PLAN

Sexual Dysfunction**Assessment**

Mr. Clements is a 46-year-old patient who was last seen in the office two months ago, when he was found to have mild hypertension and was given a prescription for propranolol (Inderal). His blood pressure today is 122/82 mm Hg.

Jack, a nursing student, talks with Mr. Clements after reading his records, which include the recent diagnosis of mild hypertension, the order for propranolol, and the current blood pressure reading of 122/82 mm Hg. The record also indicates that Mr. Clements is married and living with his wife.

Jack tells Mr. Clements of the improvement in his blood pressure since his last visit. He inquires whether Mr. Clements is taking his medication regularly. Mr. Clements reports that he has been taking his medication regularly. He relates that it scared him when his blood pressure was up because both his parents had died of strokes. Jack then inquires whether Mr. Clements has noted any side effects from the medicine. Mr. Clements says that he has not, except that he may be a little more tired than he used to be. Jack then states, "Some people find that certain blood pressure medications affect their sexual performance. Have you noticed any changes in sexual functioning since you began your medication?" Mr. Clements replies that he has had some problems achieving an erection since starting the medication.

Assessment Activities

Ascertain when Mr. Clements began noticing his inability to have an erection.

Ask Mr. Clements about his sexual relationship with his wife before taking propranolol.

Ask Mr. Clements whether he has noticed any changes in his desire for sex.

Ask Mr. Clements whether he has made any changes to his lifestyle since the first of the year.

Findings and Defining Characteristics

He responds that it was at about the same time he started taking propranolol.

He states they used to have intercourse one to three times per week.

He states that he has the same level of interest as before.

He denies any changes.

Nursing Diagnosis: Erectile dysfunction related to side effects of antihypertensive medication

Planning**Goal (Nursing Outcomes Classification)***

Patient will be able to achieve satisfactory erections.

Expected Outcomes**Sexual Functioning**

Patient will talk to his physician about this problem, and a change of medication may be warranted.

*Outcome classification label from Moorhead, S., Johnson, M., Maas, M. L., & Swanson, E. (Eds.). (2008). *Nursing outcomes classification (NOC)* (4th ed.). St Louis, MO: Mosby.

Interventions (Nursing Interventions Classification)[†]**Sexual Counseling**

Establish trust and respect with patient. Offer privacy during conversations.

Discuss possible effects of antihypertensive on sexual functioning, and encourage patient to discuss sexual concerns with physician.

Encourage patient to discuss concerns with his wife. Role-play so that patient can practise ways to approach concerns.

Rationale

Conveys sense of caring, increasing likelihood of patient's ability to express concerns fully (Ross et al., 2000)

Helps patient understand possible cause for sexual difficulties and gives patient important option to review with physician (Riley, 1999)

Many of the sexual problems in relationships involve poor communication (Finan, 1997)

Anxiety Reduction

Assure patient that other blood pressure medications are available to can maintain blood pressure control and that do not negatively affect sexual function.

Knowing that options exist and that blood pressure can continue to be safely managed gives patient sense of control (Running & Berndt, 2003)

[†]Intervention classification labels from Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (2008). *Nursing interventions classification (NIC)* (5th ed.). St Louis, MO: Mosby.

Evaluation**Nursing Actions**

At his next visit, ask Mr. Clements whether his problems have been resolved.

Patient Response and Finding

He responds that since he has been on new medication, he has had no trouble having an erection.

Achievement of Outcome

Mr. Clements reports sexual function with the new medication.

Figure 26-5 Concept map for patient with decreased libido and depression.

realistic. For example, for a patient with a nursing diagnosis of *sexual dysfunction related to dyspareunia*, you and the patient develop a goal to be free from pain or discomfort during sexual intercourse. Expected outcomes for this goal may be as follows:

- The patient will report decreased anxiety and greater satisfaction with sexual activity.
- The patient will consistently use a water-soluble lubricant with sexual intercourse.
- The patient will avoid the use of feminine hygiene products that destroy the natural flora and secretions of the vaginal walls.

A concept map is useful for organizing patient care (Figure 26-5). A concept map shows the relationship of a medical diagnosis (e.g., decreased libido and depression) with the four nursing diagnoses identified from the patient assessment data. The map also shows links and relationship with the nursing diagnosis. For example, ineffective coping affects and contributes to social isolation; as long as the patient has ineffective coping, social isolation continues or perhaps worsens.

Setting Priorities

A framework useful in guiding planning is the “PLISSIT” model developed by Annon (1976). In this model, levels of intervention are progressively more involved. *P* stands for “permission giving.” During assessment, you can bring up the topic of sexuality and give the individual permission to talk about sexual concerns. *LI* stands for “limited information,” which is basic information regarding sexuality and sexual functioning. An example is discussing nocturnal emissions with a prepubescent boy to minimize fear that might develop if the boy did not know this was a normal part of development. *SS* stands for “specific suggestions”: in this case, specific suggestions regarding a sexual concern or issue. For example, a postmenopausal woman might be concerned about her lack of vaginal lubrication, and you might suggest use of a

BOX 26-5

Community Resources Relating to Sexuality

Planned Parenthood
Sex therapists
Clinical psychologists
Social workers
Health department (often for both family planning and treatment of STIs)
Groups that provide education and services for those with particular conditions include the following:

- Canadian Diabetes Association
- Heart and Stroke Foundation of Canada
- Muscular Dystrophy Canada
- Sexual abuse support groups
- Women’s shelters (for those who have been physically abused, sexually abused, or both)
- Hotlines for help (which have lists of community support resources)

water-based lubricant during sexual intercourse. If you are not equipped to address a particular concern, you should refer the patient to another qualified health care provider. *IT* stands for “intensive therapy.” At this level of intervention, your role is to refer the patient to a qualified practitioner, such as a social worker or sexuality counsellor, for individualized therapy. The level of intervention that you plan depends in part on your own experience and knowledge. When a patient requires specific suggestions or intensive therapy, you may recommend referral to a specialist.

Continuity of Care

Planning in the area of sexuality may include referrals to community resources (Box 26-5). Sexual conflicts in marriage or

trauma related to sexual abuse or incest may necessitate intensive treatment with a mental health care provider or certified sex therapist. For women in abusive relationships, most communities have battered women's shelters that provide counseling and serve as a safe haven while they plan for their future.

❖ Implementation

Health Promotion

Because of their education, clinical expertise, and wellness orientation, nurses are among the professionals best situated to develop and implement sexual health initiatives. You can promote sexual health by identifying patients at increased risk, providing appropriate information, helping individuals gain insight into their problems, and exploring methods to deal with problems effectively. A health promotion perspective ought to guide nurses in designing a number of programs: informal educational opportunities, continuing education, peer learning activities for adolescents, community and political initiatives, and health care provider education (Beitz, 1998). Topics for education vary, depending on the nursing diagnosis (Box 26-6).

Acute Care

In general, nursing interventions that address alterations in sexuality are aimed at raising awareness, assisting in clarification of issues or concerns, providing information, or performing a combination of these. Nurses who have pursued specialized education in sexual functioning and counselling may provide more intensive sex therapy. You should recognize when an individual's needs exceed your expertise, in which case you should provide appropriate referral.

In the initial intervention, you often explore current sexual practices of the patient. The patient should be encouraged to investigate and acknowledge social and ethical values and consider the role of sexuality in his or her self-concept. When significant discrepancy exists between values and past or current practices, the patient may need referral for more intensive counselling.

Major developmental milestones (e.g., puberty or menopause) should prompt education about potential effects on sexuality. Situational crises such as a life change with pregnancy, illness, extreme financial stress, placement of a spouse in a long-term care facility, or loss and grief affect sexuality. Effects may last for days, months, or years and can generate performance anxieties that lead to continued sexual dysfunction. If an individual is prepared for possible changes in sexual functioning, performance anxieties may be minimized.

When concerns are assessed and identified, they can be addressed in the context of the patient's value system. In response to identified concerns, you may initiate discussion in pertinent areas. It may be appropriate to discuss sexual practices such as oral-genital sex or mutual masturbation as methods of expressing intimate affection when vaginal-penile intercourse is contraindicated. A partner experiencing musculoskeletal problems that cause joint pain, muscle spasms, stiffness, or problems with flexibility or mobility may appreciate a discussion of various positions for intercourse. Pillows placed about the body or under joints may reduce pain during sexual activity. Additional relief may be obtained by taking a warm shower or bath before sexual activity or using a waterbed to minimize pressure on painful joints (Nusbaum et al., 2003). Use of fantasy or a sense of playfulness may add new

* BOX 26-6

FOCUS ON PRIMARY HEALTH CARE

Sexual Health Education Topics

- Guidelines for normal development: For example, you might talk to a toddler's mother about preparing the toddler for a new baby, to a school-aged child about the appearance of pubic hair, or to a 60-year-old man about erectile difficulties. Details of physiological changes should be described as a part of general health care. Providing patient education gives permission for a patient to raise questions or concerns regarding personal functioning.
- Contraception, when talking with a patient of child-bearing age: The discussion should include such topics as the desire for children, usual sexual practices, acceptable methods of contraception, frequency of sexual activity, comfort with genital touching, comfort with sharing contraceptive responsibility with the partner, and comfort with interruption of sexual acts. You might ask, "Are you using contraceptives with your partner now?" and then follow up, on the basis of the patient's answer. For a patient who does not have a regular contraceptive method, does not have a reliable contraceptive method, or is not satisfied with the current method, the various methods of contraception should be reviewed to provide necessary information for an informed choice. The best method is the one that the patient will use consistently.
- Safer sex practices, when talking with a sexually active adolescent, with a patient who has more than one sex partner, or with a patient whose partner has multiple sexual partners: You should provide information regarding STI symptoms and transmission, use of condoms, and risky sexual activities (e.g., trauma from penile-anal sex). A topic to consider in discussing sexual relating is the emotional risks within a relationship. Role-play can be a useful educational tool for helping a person learn to say no or negotiate with a partner to use a condom.
- The need for regular physical examinations: Regular health examinations are important for maintaining sexual health. The annual health examination also provides an easy opportunity to discuss contraception and safer sex practices. Regular clinical breast examinations, mammography, and Papanicolaou (Pap) smears are important for women, as are testicular self-examinations for men.

romance or stimulation to a long-term relationship. A couple may need confirmation or assurance that the acting out of nonharmful fantasy is normal and healthy.

Restorative Care

In the patient's home, you can help create an environment that is comfortable for sexual activity. This may involve recommending ways to arrange the bedroom to accommodate an individual's limitations. For example, a patient in a wheelchair may prefer to move the chair close to the side of the bed at an angle that allows for more ease in touching and caressing. Suggestions regarding how to accommodate barriers such as Foley catheters or drainage tubes can contribute to enhanced sexual activity.

In the long-term care setting, facilities should make proper arrangements for privacy during patients' sexual experiences (Luekenotte, 2000). The ideal situation is to set up a pleasant

Figure 26-6 Critical thinking model for sexuality evaluation. *HIV*, Human immunodeficiency virus; *STI*, sexually transmitted infection.

room that can be used for a variety of activities but may also be reserved for private visits with a spouse or partner. If this is not feasible, you can make arrangements for the roommate of a patient to go to another place, in order to allow a patient and his or her partner time alone.

❖ Evaluation

Patient Care

To determine whether goals and outcome criteria have been met, you review patients' responses to interventions (Figure 26-6). Critical thinking ensures that you apply what you know about sexuality and the patient's unique situation.

In follow-up discussions with the patient or spouse, you determine whether goals and outcomes have been achieved. Patients can be asked to relate risk factors, verbalize concerns, share stories of their experiences, and clarify their level of satisfaction. You can also observe behavioural cues, such as eye contact, posture, and extraneous hand movements, that indicate comfort or are suggestive of continued anxiety or concern as topics are addressed. As outcomes are evaluated, you, the patient, and the spouse may need to modify expectations or establish time frames in which to achieve the target goals. All involved may need to be reminded of the individual nature of sexual expression and the multiple factors that affect perceptions and responses. Sexual wellness is not an absolute. An individual must define what is acceptable and satisfying. The partner's level of sexual satisfaction must also be considered. Sexual performance is seldom the exclusive focus of sexual

satisfaction. Open communication and positive self-esteem are essential factors in effectively resolving concerns.

Patient Expectations

In evaluating the outcomes of interventions related to sexuality, you must consult with the patient. Resolution of sexual concerns must meet the patient's perceptions of improvement. A patient must define what is acceptable and satisfying. In considering the status of sexual health, the patient's partner's perceptions of sexual satisfaction are also significant.

❖ KEY CONCEPTS

- Sexuality is related to all dimensions of health; therefore, as a part of nursing care, sexual concerns or problems should be addressed.
- Sexuality is a part of each individual's identity and includes sexual identity, gender identity, and sexual orientation.
- Attitudes toward sexuality vary widely and are influenced by religious beliefs, society's values, the family, and other factors.
- Nurses' attitudes toward sexuality also vary and may differ from those of patients; nurses should be sensitive to patients' sexual preferences and needs.
- Sexual development is a process beginning in infancy and involves some level of sexual behaviour or growth in all developmental stages.
- The physiological sexual response changes with aging, but aging does not lead to diminished sexuality.
- Sexual health involves physical and psychosocial aspects and contributes to an individual's sense of self-worth and positive interpersonal relationships.
- Sexual dysfunction can have an easily identified cause or varied and complex causes.
- Interventions for sexual dysfunctions depend on the condition and the patient; interventions may include giving information, teaching specific exercises, improving communication between partners, and referral to a knowledgeable professional.
- Choice and use of contraceptive methods are affected by desire for children, usual sexual practices, acceptable methods of contraception, frequency of sexual activity, comfort with genital touching, comfort with sharing contraceptive responsibility with the partner, and comfort with interruption of sexual acts.
- A brief review of sexuality should be included in every nursing assessment of a patient's level of wellness.
- Most nursing interventions to enhance a patient's sexual health involve providing information and education.

❖ CRITICAL THINKING EXERCISES

1. Your current clinical experience is in a community health care setting. You are conducting the initial interview with a 48-year-old man who started taking antihypertensive medications two weeks ago. You take his blood pressure and find it to be 136/74 mm Hg. You ask him how he has been doing since his last visit. He looks down at the floor and says, "Oh, okay, I guess. Seems like I'm just getting old now." What kind of follow-up would be indicated on the basis of this information?
2. You are assigned to care for a 15-year-old girl who was admitted after a motor vehicle accident. Yesterday she underwent internal fixation of a fractured ankle. In gathering her nursing history, you explore sexuality and learn that she has just recently become sexually active with her boyfriend of three

months. When you ask about safer sex and the use of birth control, she tells you that she knows she does not have to worry about STIs with him because he is just not one of those kinds of boys. In regard to birth control, she says that her boyfriend has reassured her that because he is pulling out before ejaculation, she does not risk becoming pregnant. How would you proceed?

3. You are working on a rehabilitation unit and caring for a 67-year-old man who had a stroke three weeks ago. He shares a room with another man who is recovering from a stroke. Your patient has been progressing in his self-care skills and is now able to get around with a cane, feed himself, and perform most of his bathing. His wife is in fairly good health, and the plan is for him to return home within the next one to two weeks. As you work with him one morning, he says to you, "You know, one of the things that is hardest about being here is not being able to sleep in the same bed as Greta. I miss her so much. Even though she visits every day, it is just not the same." How would you explore his comment, and what planning would you consider?

❖ REVIEW QUESTIONS

1. Gender identity is the individual's
 1. Sexual behaviour
 2. Sexual orientation
 3. Sense of being male, female, or some combination
 4. Sense of preferring one sex over the other
2. Sexual health refers to
 1. Having no STIs
 2. Awareness of and positive attitudes toward sexual functioning
 3. Using contraception consistently
 4. Sexual activity with multiple partners
3. Inability or difficulty in sexual functioning caused by numerous factors is called
 1. Sexual behaviour
 2. Sexual response
 3. Sexual orientation
 4. Sexual dysfunction
4. A major problem in dealing with STIs is that
 1. Symptoms are often absent or go unnoticed
 2. Most STIs cannot be treated with antibiotics
 3. Little is known about how they are transmitted
 4. Little can be done to help
5. The most common bacterial STI is
 1. Syphilis
 2. Genital chlamydia
 3. Gonorrhea
 4. HIV infection and AIDS
6. Of the following methods of contraception, which two require a health care provider's intervention?
 1. Diaphragm and intrauterine device (IUD)
 2. Condoms and hormones
 3. Cervical caps and condoms
 4. Sterilization and vaginal spermicides

7. Which of the following is the most effective contraception method for women?
 1. Female condom
 2. Birth control pill
 3. Contraceptive sponge
 4. Vaginal spermicide
8. The most valuable tool that you can use when providing sexual health care is
 1. Knowledge of right and wrong sexual behaviours
 2. Effective, nonjudgemental communication
 3. Nursing diagnoses
 4. Firm personal convictions about what constitutes normal sexual behaviour
9. When you are gathering a sexual history from an older adult, you must keep in mind that
 1. Older adults do not usually participate in sexual activity
 2. Older men always lose fertility
 3. Older adults may have difficulty discussing intimate matters
 4. Both older men and women are sexually dysfunctional
10. A useful framework for the nurse to guide planning and set priorities about sexual activity for a patient is
 1. The PLISSIT model
 2. The NANDA International guidelines
 3. The *Nursing Interventions Classification* (NIC) and *Nursing Outcomes Classification* (NOC) guidelines
 4. Your own theory of sexual behaviour

Spiritual Health

Written by Barbara Pesut, RN, PhD, Corinne Crockett, MHcS(N), RN, RScP, and Jeanette Vinek, RN, RScP, BScN, MHScN

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Describe the historical influences of spirituality and religion on nursing.
- Discuss research findings that suggest a relationship between spiritual practices and patients' health status.
- Discuss the relationship between spirituality and nursing theory.
- Compare and contrast the concepts of religion and spirituality.
- Describe how spirituality may facilitate coping during times of illness or suffering over the life journey.
- Describe the relational attributes that facilitate spiritual nursing care.
- Discuss the process and qualities of spiritual nursing care.
- Discuss an ethical approach to spiritual nursing care.
- Discuss the role of the nurse in providing spiritual nursing care.
- Describe a process for understanding patients' spirituality.
- Discuss appropriate ways to facilitate patients' spiritual practices.
- Describe when it is necessary to involve a spiritual leader or pastoral care.
- Reflect on how to determine if your spiritual care has been therapeutic.

The word *spirituality* is derived from the Latin word *spiritus*, which refers to breath or wind. The spirit gives life to, or animates, a person. Spirituality has been described as the centre of all aspects of a person's life, whatever gives that person ultimate meaning (Sessanna et al., 2007). Spirituality can be an important factor that helps individuals achieve the balance needed to maintain health and well-being and to cope with illness. Caring for a patient's spiritual needs means caring for the whole person, accepting his or her beliefs and experiences, and helping with issues concerning meaning and hope. Expert nurses help patients use their own spiritual resources as they identify what is meaningful in their lives and cope with the effects of illness and life stressors.

Historical Perspectives

Nursing has a rich spiritual heritage. Within this heritage, spirituality was most recognizable within religion. Religion provided a lens through which to acknowledge spiritual needs, express spiritual care, and pursue spiritual health. Organized nursing originated from religious orders, in which nuns were primarily responsible for providing nursing care. In Canada, the earliest nurses belonged to Roman Catholic orders devoted to care of the sick: most notably, the Sisters of Charity of Montreal (Grey Nuns), an order founded by Marie Marguerite d'Youville in 1737 (Paul, 2000). This noncloistered order was responsible for bringing a Judeo-Christian model of nursing care to the most remote areas of western and northern Canada. Florence Nightingale's ideas of modern nursing were first taught in London in 1860. Her model of Western nursing, rooted in Christianity, was spread around the world during the colonial era (Paul, 2000). Canadian missionary nurses were among those who brought Florence Nightingale's ideas of modern nursing methods to China, India, Japan, and Korea in the first half of the twentieth century (Grypma, 2008).

Religion was at the core of early nursing philosophies and practice until the nineteenth century (McSherry, 2001). But during the late nineteenth and early twentieth centuries, confidence in religion was replaced by confidence in medical science. Religious aspects of care became less visible. However, over the past several decades, many nurses became dissatisfied with a purely medical approach to care, partly because people realized that scientific research could not answer all the existential questions raised by patients (McSherry, 2001). Nurses felt a spiritual gap in the profession and began to find ways to articulate and incorporate spirituality into practice and research. Spirituality was conceptualized as broader than any particular religion or culture. Between 1980 and 2000, renewed interest in spirituality was reflected by an increase in nursing literature on spirituality, as well as a growing interest in parish nursing as a way for faith communities in Canada to reclaim their healing mission (Miller, 2004; Olson et al., 1998).

Canadian nursing scholarship has made important contributions by emphasizing the relationship between spirituality, religion, health, and culture (Kulig et al., 2004; Labun & Emblen, 2007; Pesut et al., 2008). For example, in their study of spirituality and health in Punjabi Sikh living in British Columbia, Labun and Emblen (2007) stated that an understanding of the interplay of spirituality, religion, and health informs culturally competent care. Just as Canadian nurses must understand cultural influences in health and illness, they must also recognize the need for sensitive, safe, and ethical nursing care in which patients' spiritual needs and resources are recognized and supported (Box 27-1). Because Canada is a pluralistic society in which diversity is valued, Canadian nurses must recognize how diverse views influence the way patients (and nurses) view spirituality (Pesut, 2006; 2009).

Spirituality and Health: Empirical Evidence

Spiritual health has been defined as "a connectedness with self, others, and the sacred that transcends and empowers the self" (Como, 2007, p. 226). Spiritual needs may increase as health declines (Bruce et al., 2011; Carson & Koenig, 2008; McSherry, 2006). There is increasing evidence that spirituality

* BOX 27-1 CULTURAL ASPECTS OF CARE

In caring for patients from different cultures, it is important that you take into account their cultural understandings of spirituality and religion. You must determine what is important in their lives and what provides them with inner strength and meaning. Patients are often attempting to find meaning in the changing circumstances of their health and illness but that meaning will differ depending on their values and beliefs. For example, Shih et al. (2009) explored the spiritual needs of older Taiwanese patients with terminal cancer using participant observation and in-depth interviews. They suggested that caring for the body and transcending worldly being were common patterns and emphasized, among other things, the important role of the funeral ceremony in purifying the soul and contributing positively to the afterlife. Similarly, Mok, Wong, and Wong (2010) explored through interviews the meaning of spirituality and spiritual care among Hong Kong Chinese terminally ill. An important finding from this study was that all participants had difficulty understanding and expressing spirituality. Further, they did not expect spiritual care from nurses but desired quality interpersonal care. Reimer-Kirkham (2009) explored the negotiation of religious and spiritual plurality in health care encounters and used the example of Sikh patients to highlight how lived religion is a moral code that informs all of life and has important implications for ethical nursing care.

Implications for Practice

- Explore the spirituality of patients within the contexts and meanings of their own cultures. Spirituality may not be the language that is most familiar to them. It is always appropriate to explore the meaning of health and how patients achieve balance, stability, peace, or comfort in their lives.
- Offer a universal and holistic approach to patients by demonstrating caring and by using therapeutic communication techniques.
- Promote an environment during assessment in which human rights, values, customs, and spiritual beliefs are respected.
- Include appropriate spiritual or religious care providers.
- Avoid the use of language that alienates patients or discriminates between different religions (e.g., asking whether the patient wants someone from his or her "faith community" to visit, rather than "temple," "church," or "synagogue").
- Understand that different cultures and religions have ethical codes that are an important part of ethical nursing care.

(2009). Spiritual needs of Taiwan's older patients with terminal cancer. *Oncology Nursing Forum*, 36(1), E31–38.

has the potential to mobilize personal capacities, illness-coping strategies, and positive health behaviours (Como, 2007; Krok, 2008; Lawler-Row & Elliott, 2009; Levin, 2010; Vespa et al., 2011; Whelan-Gales et al., 2009). For example, research involving 263 patients with cancer found that those who reported healthy inner spirituality, spiritual coping, and spiritual well-being were less likely to experience depression and intrapersonal/interpersonal conflicts (Vespa et al., 2011). Positive spiritual and religious coping has also been linked to a

sense of calmness, peace, decreased anxiety, and improved mood, which in turn correlated with an improved tolerance to pain (Wachholtz et al., 2007). An exploration of the beliefs of 228 hospitalized patients in Australia found that 80% of respondents felt that religious and spiritual beliefs aided in the healing process by providing psychological support, an improved sense of well-being, and support in maintaining a healthy lifestyle (Hilbers et al., 2010, p. 5). Recent research into the relationship between spirituality/religion and mental health suggested that religion could have a protective effect, although caution must be exercised with patients whose psychiatric concerns include religious ideations (Levin, 2010). Among older adults, spiritual well-being and use of prayer were positively related to physical and psychological well-being (Lawler-Row & Elliott, 2009).

Mind-Body Connection and Psycho-Neuro-Immunology

Increasingly, researchers are trying to determine why spirituality may be related to health, particularly from a physiological perspective. The number of studies exploring the mind-body connection, and psycho-neuro-immunology in particular, has increased exponentially. The question of whether the relationship between spirituality and health is simply a placebo effect has arisen in the literature (Breslin & Lewis, 2008). Current research into the placebo effect, once considered proof of hypochondria or hysteria, has focused on the power of the mind to affect the health of the body (Kradin, 2010; Lidstone & Stoessl, 2007). Thoughts and beliefs mediate chemical responses in the body that support or inhibit health and healing (Lidstone & Stoessl, 2007). Try the exercise in Box 27-2 to get a sense of the mind-body connection.

Physical health is affected by beliefs, expectations, and thoughts. Although the mechanisms are not yet fully understood, body, mind, and spirit are interconnected; when one facet of a person faces a challenge or receives support, the others are affected. This idea is commonly referred to as **holism**. For example, cardiovascular health and immune function are affected by stress (Carson & Koenig, 2008). Recent research on wound healing and stress found that both psychological and physiological stress delay wound healing and increase the potential for wound infection (Gouin & Keicolt-Glaser, 2011). Research such as this suggests that spiritual and religious rituals may do more than just provide a comforting effect. Prayer, meditation, contemplation, sacraments, rituals,

and other practices that support spiritual and religious expression may indeed reduce stress and support health and healing (Tuck et al., 2006). Understanding the role spirituality plays in a patient's life and which spiritual practices are important to them allows the nurse to support the health and healing of those receiving care. This is the reason why it is important to consider spirituality in the context of nursing theory, a topic that we turn to next.

Spirituality and Nursing Theory

Nursing theory is a logical structuring of ideas that inform what we believe nursing to be and how nurses go about their work. One of the first formal theoretical thinkers in nursing was Florence Nightingale (Meleis, 1997; Thorne, 2003). Her theoretical thinking was largely informed by her beliefs about God and natural law (Calabria & Macrae, 1994). During the late 1950s and early 1960s, nurses began to construct theoretical models of nursing, and over the next two decades nurses produced over 20 new models (Thorne, 2003). Some of these models included spirituality as an aspect of nursing practice (Martsolf & Mickley, 1998).

One of the ways that nurses have developed theory in relation to spirituality has been through nursing diagnoses. Although three nursing diagnoses related to spirituality are currently accepted by the North American Nursing Diagnosis Association International (2009)—*readiness for spiritual well-being*, *spiritual distress*, and *risk for spiritual distress*—their use in nursing practice is debated. Some scholars are challenging the idea that spirituality should be thought about in the context of a problem-solving process—that is the idea that spirituality should be thought of from the perspective of problems that can be diagnosed and solved. For example, Pesut (2008b) urged nurses to “resist the notion that there is some idealized spiritual state ... the absence of which necessarily dictates some pathological process” (p. 172). Nurses need to be cautious about creating criteria that indicate normal spiritual health, particularly those based on positive emotions such as peace and happiness (Pesut & Sawatzky, 2006). This is particularly important in light of research findings that suggest that individuals, even at end of life, may not feel comfort or peace but still experience spiritual growth (Kruse et al., 2007). The mysterious nature and experience of spirituality must not be reduced to problems or nursing diagnoses. That is why this is one of the few chapters in this textbook that does not use the nursing process.

Spirituality and religion have informed nursing theory in important ways. Nurses care for individuals during times of sickness and death. Therefore, nursing theory tries to answer fundamental questions about the nature of persons, about health, and about the environment (Meleis, 1997). Historically, these questions have been answered through religious or philosophical thinking, so it is not surprising that many nurses draw on these beliefs to inform nursing theory. Nursing models have been derived from Western Christian religious perspectives (e.g., Bradshaw, 1994; O'Brien, 2008) and from Eastern Chinese and Indian perspectives (e.g., Martha Rogers, Margaret Newman, and Rosemary Parse [as cited in Sarter, 1988]).

A debate has emerged in nursing about whether spirituality should inform nursing theory. There are those who believe that spirituality is an essential part of holistic care and so should be a fundamental consideration in nursing care. Others have

► BOX 27-2

Mind-Body Connection: Try It for Yourself

Settle back and gently close your eyes. Imagine a plump, juicy, yellow lemon. Holding the image of the luscious lemon in your mind, imagine picking up the lemon and smelling it. Imagine cutting the lemon in half, with the juices squirting out. In your mind's eye, bring half of the cut lemon to your lips and squeeze the juice into your mouth.

What happened? Did you salivate? Some people even experience a puckering of their mouths.

This is an example of the mind-body connection that demonstrates the effect of a thought on the body. Spiritual practices, which support feelings of transcendence, connection, well-being, and calm, support healing.

argued that in a diverse society, not everyone believes in spirituality, so nursing theory should be based on a naturalistic model (meaning it should deal only with what can be verified empirically) (Hussey, 2009; Paley, 2008). This is an important question for nurses to think about. However, it would be difficult to exclude spirituality from nursing theory when it is important to many patients (Pesut, 2008a). The more important question becomes how nurses can include it in a way that it is sensitive to the many beliefs about spirituality that exist in a diverse society (Pesut, 2010). This will be discussed further under the ethical aspects of spiritual care.

Conceptualizing Spirituality and Religion

Conceptualizing is an important part of nursing thinking. Conceptual work consists of creating definitions that become tools for nurses that bridge between the broader world of ideas and the unique nurse–patient interaction (Thorne, 2005). Over the past two decades, nurses have struggled to create a definition of **spirituality** for nursing practice. Several integrative reviews of spirituality in health care literature have identified the following common themes: meaning, purpose, hope, connectedness, relationship, transcendence, existential experiences, and power/force/energy (Chiu et al., 2004; McCarroll et al., 2005). However, trying to define spirituality has been challenging. If we try to include all of the diverse ideas about what spirituality is, the concept becomes too vague to be useful for nursing practice or knowledge development. You only have to think about the themes identified above to realize that they cover the entire human experience. This has been a real problem for the development of practice-based knowledge about spirituality.

Many use the terms *religion* and *spirituality* interchangeably. Although closely associated, these terms are not synonymous. **Religion** is an organized system of beliefs concerning the cause, nature, and purpose of the universe, especially belief in or the worship of God or gods (Andrews & Boyle, 2007). It is a structured search for the spiritual and an outward expression of spirituality (Emblen, 1992). Religious practice encompasses spirituality, but spirituality need not include religious practice. A person's spirituality may be expressed in religious and philosophical beliefs and practices, and these may differ widely, depending on the person's race, gender, social status, religion, ethnicity, and experience (Johnston Taylor, 2002). Although nursing literature draws a clear distinction between spirituality and religion, the boundaries are much less clear in actual experience (Macrae, 2001). For many patients, the term *spirituality* may still be closely related to religion, and many individuals' spiritual practices are drawn from a variety of religious traditions (Pesut et al., 2008b). Indeed, 53% of Canadians still describe spirituality in traditional terms such as *prayer*, *religion*, and *a power beyond* (Bibby, 2006).

Another common term individuals use to express their spirituality is that of **faith**. Faith is often used in two ways: as a cultural or institutional religion, such as Judaism, Buddhism, Islam, or Christianity; and as a relationship with a divinity, a higher power, an authority, or a spirit. Faith may also be the manner in which a person chooses to live life, apart from religion or spirituality. Faith in this sense enables action. For example, a person might believe that having a positive outlook on life is the best way to achieve life's goals. Faith may also involve a sense of **transcendence**: an awareness of something that a person cannot see or know in ordinary physical ways (Perry, 2004) or an experience of fullness that goes beyond

daily life (Taylor, 2007). This experience does not necessarily need to be understood in relation to God—it may be in relation to the universe, nature, or humanity. It gives purpose and meaning to an individual's life, allowing for action. For example, in patients with advanced cancer, faith may provide significant strength and resources to cope with their illness (Lin & Bauer-Wu, 2003).

An important principle to consider when conceptualizing spirituality is respect for diversity. Part of respecting diversity is recognizing that some individuals might be offended by the claim often made in nursing literature that all individuals are spiritual (Pesut et al., 2009). Some individuals either do not believe in the existence of God (**atheist**) or believe that any ultimate reality is unknown (**agnostic**) and so may resist the idea that all persons have a spiritual nature. Thorne (2005) has encouraged nurses to remember that the purpose of conceptualizing is to support nursing's service to society. Conceptualizing about spirituality in nursing must serve a diverse society.

Spirituality and the Life Journey

Children's ideas of a higher power or supreme being are often based on what is presented to them in their homes or religious community. Their spirituality develops as they learn about themselves in relationship with others. Adolescents may reconsider their childhood concept of a spiritual power and, in the search for an identity, may question values and practices. Many Canadian teenagers and young adults who have been reared in a religious tradition "drop out" of their religious system as they search for a personalized belief system and clearer meaning of life (Bibby, 2002). Many adults experience spiritual growth by entering into lifelong relationships. An ability to care meaningfully for others and the self is evidence of a healthy spirituality. Older adults often turn to important relationships and the giving of themselves to others as spiritual tasks. As people mature, they often turn inward to enduring values and to a concept of a supreme being or a higher meaning that has been sustaining and meaningful. A healthy spirituality in older adults is one that gives peace and acceptance of the self. A positive relationship to a higher power may help to protect older adults from the negative effects of loss and changing identity that occur with aging (Griffith et al., 2007). (See Box 27-3 for a Focus on Older Adults).

Along this life journey, spirituality and religion can play an important role in the lives of individuals. For example, they can provide answers to the some of the big questions in life such as "What is life all about? How should I live a good life? What happens to me after I die?" Communities of faith can provide important connections and social support. Spiritual practices help individuals to grow and transform as persons. Spiritual experiences provide a sense of fullness that creates a sense of transcendence and connection to something greater (Taylor, 2007).

However, few individuals experience life's journey without facing an unexpected or chronic illness or injury resulting in suffering and loss. Such events can lead to both spiritual challenges and transformation. Spiritual dimensions of the illness experience may include reconsidering beliefs about life; maintaining spiritual or religious practices; connecting with God and significant others; and finding balance, courage, and growth (Van Leeuwen et al., 2007).

In the face of suffering, individuals may feel alone or even abandoned by God. They may question their spiritual values

* BOX 27-3 FOCUS ON OLDER ADULTS

Factors That Put Older Adults at Risk

- Loneliness and social isolation
- Hopelessness in the face of losses or terminal illness
- Anxiety
- Depression

Interventions to Facilitate Connectedness

- Include family in activities and plans
- Place memorabilia in view of the patient
- Talk about things that are meaningful and reminisce
- Bring pets in to visit
- Provide access to nature
- Refer to mental health providers for cognitive behavioural therapy
- Physical touch, massage
- Aromatherapy and music

Interventions to Facilitate Hope

- Develop caring relationships and provide continuity of care providers
- Life-review therapy—help to identify significant losses
- Use past experiences to reinforce coping skills
- Promote a restful and relaxing environment
- Implement relevant rituals and traditions

Source: Meraviglia, M., Sutter, R., Gaskamp, C. D., Adams, S., & Titler, M. G. (2008). Evidence-based guideline: Providing spiritual care to terminally ill older adults. *Journal of Gerontological Nursing*, 34(7), 8–14.

and beliefs, raising questions about their way of life and purpose for living. Anger is not uncommon, and patients may express anger toward God, their families, themselves, or health care providers. People also look for ways to remain faithful to their beliefs during their suffering. They may pray, attend religious services, or reflect on the positive aspects of their lives. Individuals who have a sense of spiritual health, who feel connected with a higher power and other people, and who are able to find meaning and purpose in life are better able to cope with chronic illness; better coping helps them achieve their potential and enhances quality of life (Adegbola, 2006; Narayanasamy, 2004).

Terminal illness is the end of the life journey and brings unique struggles. As the physical body dies, individuals are confronted with questions about the meaning of their life and what comes after. Fears of physical pain, isolation, and losing control are common, both for oneself and for one's family. Spiritual beliefs and practices often provide a source of comfort and strength, and individuals may experience end of life as a time of positive spiritual transformation (Alcorn et al., 2010). Tanyi and Werner (2008) interviewed 16 women with end-stage renal disease and found that spirituality helped them accept illness and mortality, find strength and understanding during the experience, and counter negative emotions such as anger, fear, and depression.

The spiritual framework of coping illustrated in Figure 27-1 provides an overview of how spirituality relates to coping and health. An illness or injury would constitute a stressor. The experience of that illness or injury is shaped both by personal

* BOX 27-4 RESEARCH HIGHLIGHT

Mapping the Process and Qualities of Spiritual Nursing Care

Research Abstract

Carr (2008) explored the meaning of spiritual nursing care using in-depth, open-ended interviews in an oncology setting. Her 29 participants were nurses, patients, family members, and administrators. Using phenomenological analysis, she constructed an account of spiritual nursing care that, at the core, was developing caring relationships and fostering connections. Receptivity, humanity, competency, and positivity were essential characteristics for spiritual care to be realized. Receptivity entailed being open and present and recognizing subtle cues. "Big things can come out of small talk" (p. 693). Humanity entailed allowing both the nurse and the patient to bring their identities to the encounter. Competency entailed giving good physical care. Positivity entailed exchanging a form of energy that was hopeful, positive, humorous, and characterized by faith.

Evidence-Informed Practice

- Be open and receptive to those under your care.
- Listen well, and listen for what is not said.
- Engage in small talk as a safe entry into more significant discussions.
- Do the little things that make a difference.
- Provide excellent physical care.
- Nurture your own faith so that others can share the "positivity" it produces.

factors and how one appraises the event. For example, an individual might attribute the cause of an illness to a punishment by God for a sin they committed and this would magnify the stressor. The effect of the stressor is also determined by personality factors such as problem-solving styles or hope and religious influences such as doctrinal beliefs and religious orientation. Perceptions of God, and in particular whether God is more likely to be punishing or loving in the face of suffering, greatly influences appraisals of illness. How one appraises the stressor contributes to the effect of that stressor. Individuals can then enact spiritual coping behaviours, both corporate and private, and work to establish spiritual connections. These coping strategies may in turn contribute to enhanced meaning making and well-being.

What do patients expect from nurses in the area of spiritual care? (See Research Highlight in Box 27-4.) Although nurses are not typically seen as primary spiritual care providers, patients do appreciate having nurses know about their spirituality and showing spiritual concern. This is most often the case if spirituality is important to the patient, in the context of life-threatening illness, and if there is some relationship present (Johnston Taylor, 2007b). In a recent study of Chinese individuals with terminal illness, participants suggested that although they did not expect nurses to provide spiritual care, a compassionate environment that promoted hope and acceptance supported their spirituality (Mok et al., 2010). Similarly, another study that explored spiritual care in female patients on dialysis suggested that patients appreciated nurses who cared, who tried to understand their spirituality, and who helped support

Figure 27-1 The spiritual framework of coping (an adaptation and application of the transactional model). **Source:** From Gall, T. L., Charbonneau, C., Clarke, N. H., Grant, K., Joseph, A., & Shouldice, L. (2005). Understanding the nature and role of spirituality in relation to coping and health: A conceptual framework. *Canadian Psychology*, 46(2), 88–104. appropriate spiritual activities (Tanyi et al., 2006). A recent content review of spiritual care by nine nursing experts affirmed that practices such as listening, supporting spiritual practices, and making referrals are important when supporting patients' spirituality (Johnston Taylor, 2008).

Critical Thinking

At the core of nursing, and indeed at the core of all human service professions, is a commitment to caring for each person as a unique and inherently valuable individual. In the case of spirituality, this commitment begins with a respect for each person's beliefs. Fundamental differences exist in the ways people experience the world and find meaning in that experience. Critical thinking in the context of spiritual care entails two important processes. First, it means gaining an understanding of the patient. This includes their spiritual and religious values, beliefs, and experiences and how those are influenced by their current circumstances. Naturally, the depth of this assessment must be sensitive to the circumstances (e.g., patients coming in for day surgery as opposed to palliative care) and the depth of the nurse–patient relationship. Second, a critical thinking approach to spiritual care entails ensuring

that the care provided is both ethical and based on the best available evidence. This also entails knowing the appropriate criteria on which to base an evaluation of nursing care.

Understanding Patients' Spirituality

You will note that we have chosen not to use the language of assessing spirituality. Spiritual care is different from the physical aspects of care. Spirituality contains an element of mystery that cannot be assessed and treated in the same way that you might treat a physical problem, such as a pressure ulcer. Diagnosing and intervening in a patient's spirituality could be considered disrespectful and intrusive. Instead, nurses should think about *understanding* rather than assessing patients' spirituality. It could be thought of as a series of conversations whereby nurses seek to understand what is important and meaningful to individuals. The depth of that conversation will rest largely on the circumstances the patient is facing and the extent of relational development. But even more important, the nurse should discover those values and beliefs that are important to take into account in health care. Does the patient have beliefs that will influence important health care decisions? Are there religious rituals or restrictions that should inform care? Without knowing these details, the nurse risks harming the

patient. For example, a nurse who removes sacramental garb or provides food that is prohibited may actually be contributing to the breaking of religious law and thus be seen to be harming that individual's spirit.

In these conversations, the nurse is not the expert but rather a co-learner in the mysteries of life. This kind of work generally consists of quiet conversations, effective listening, and communication through presence and touch (Draper & McSherry, 2002). In many cases, nurses would say that they are the learners. Patients teach them about life as they share their stories of transition and suffering. Above all, the process of learning about a patient's spirituality should be grounded in an understanding of compassion and community (Heliker, 1992). The term **compassion** comes from the Latin words *pati* and *cum*, meaning "to suffer with." *Community* is derived from the Latin word *communio*, meaning "fellowship." To be compassionate is to "enter into places of pain, to share in brokenness with other human beings" (Heliker, 1992). To practise compassion as a nurse requires awareness of the human tie between patients and a healing community.

However, even though understanding is a relational and evolutionary process, it is still important that the nurse have some form of systematic approach to ensure that critical information is obtained. When patients enter a health care facility, it is essential to obtain information about their religious and spiritual beliefs and practices. This has been referred to as a spiritual screening and seeks to discern whether spirituality and religion are important to the individual and, if so, what beliefs or practices are most important to take into account in the context of care.

Numerous tools are available to enable nurses to gain a deeper understanding of patients' spirituality (e.g., see Johnston Taylor, 2002). Johnston Taylor (2002) has formulated one such tool, which builds upon the work of previous nursing scholars and can be used to start to question the spiritual health of a patient (Box 27-5).

Remember that how this tool is used will depend on the circumstances. It may not be relevant to have answers to all of the areas listed. You may need to modify certain questions in light of the patient's beliefs. For example, if the patient claims

► BOX 27-5 Procedural Guideline

Understanding a Patient's Spirituality

Spirit-Enhancing Practices or Rituals

- How do you express your spirituality (or philosophy of life)?
- What spiritual or religious practices or activity are important to you?
- How has being sick affected your spiritual practices?
- How does being sick have an impact on your praying (or other rituals)?
- How and for what do you pray?
- What spiritual or religious books are helpful to you?
- What effects do you expect your illness to have on your spiritual practices or beliefs?
- What kinds of readings, artwork, or music are inspirational for you?
- How do Holy Scriptures help you in daily life?
- How can I as a nurse help you with your spiritual practices?
- How do your religious practices help you to grow spiritually?

Involvement in a Spiritual Community

- How involved in a spiritual or religious community are you?
- What kind of relationship do you have with the leader of your spiritual community?
- In what ways does your spiritual community help you when times are bad?
- Are you having difficulty carrying out your religious duties?

Sense of Meaning

- What gives most meaning to your life?
- What is the most important thing in your life?
- What are your thoughts about, or explanations for, suffering? Are these beliefs helpful?
- What do you see as the plan or purpose for your life?
- Have you been able to answer any of the "why" questions that often accompany illness?
- What, if any, have been the good outcomes of having this difficult time in your life?
- What, if anything, motivates you to get well?

Giving and Receiving Love, or Connectedness to Self (Degree of Self-Awareness) and Other

- What do you do to show love for yourself?
- What are some of the most loving things that people have done for you?
- What are the loving things that you do for others?
- How do others help you now? How easy is it to accept their help?
- For what do you hope? How do you experience hope?
- How have you experienced forgiveness during your life/illness?

Sources of Hope and Strength

- What helps you to cope now?
- What (or who) is your source of hope? of strength? How do they help?
- To whom do you turn when you need help? Are they available?
- What helps you most when you feel afraid or need special help?
- How can I help you maintain your spiritual strength during this illness?
- To what degree do you trust your future to God?
- What brings you joy and peace in your life? What do you believe in?
- What do you do to make yourself feel alive and full of spirit?

Linkage Between Spirituality and Health

- How does your spirituality affect your experience of being sick?
- How has your current situation/illness influenced your faith?
- How has being sick affected your sense of who you are (or how has being sick affected you spiritually)?
- What has bothered you most about being sick (or in what is happening to you now)?
- What do you do to heal your spirit?
- Has being sick (or your current situation) made any difference in your feelings about God or your faith experience (or in what you believe)?
- Is there anything especially frightening or meaningful for you now?
- Do you ever wish for more faith to help you with your illness?
- Has being ill ever made you feel angry, guilty, bitter, or resentful?

to be spiritual but not religious, and if God is not part of that spirituality, you may need to delete certain questions. The key is to be sensitive to what patients want to tell you and to be a good listener. If religion and spirituality are important to their lives, and if they find you a compassionate and open listener, you will be more likely to gain meaningful information.

Further, it is important to think about how and when the information will be gathered and recorded. Numerous nurses are involved in one patient's care. Having all of these nurses inquire using this tool is not appropriate. For each nursing context, it is important to ask the following questions and to create policies and procedures that address these questions.

- Who should be collecting this data?
- How extensive should the assessment be in light of the clinical context?
- At what point in the care trajectory should this information be obtained?

There is a fine balance between establishing a relationship prior to asking questions in this area and making sure that you know enough to provide safe and ethical care. Which responses should be documented so that the information is available to all health care providers and which responses should be held in confidence? You can imagine yourself responding to questions such as "What feelings do you have after you pray?" and how you would feel if your responses were made available to everyone who had access to your health care record. Pondering and answering these questions in your health care context is part of expert nursing thinking and critical judgement.

This more in-depth understanding of a patient's spirituality has certain goals that should guide these conversations:

- Invite patients to share their spiritual beliefs and values.
- Learn about those beliefs and values.
- Open an opportunity for compassionate care.
- Empower patients to draw on their resources for healing and acceptance.
- Identify practices and beliefs that are important for the plan of care.
- Identify those patients who would benefit from a referral to a spiritual care provider. (Puchalski et al., 2009)

Ethical Spiritual Care

The *Code of Ethics for Registered Nurses* (Canadian Nurses Association, 2008) requires nurses to treat all patients with dignity and respect. In providing nursing care, you must not discriminate on the basis of spiritual beliefs, age, ethnicity, marital status, gender, race, sexual orientation, health status, or disability. However, for many, discrimination is not a conscious process but rather an unchallenged set of biases that cause us to react to others in less than caring ways. Therefore, an important part of ethical spiritual care is constantly working with your own potential biases as a nurse. This is more commonly known as reflective practice. In the process of delivering care, the nurse remains open to internal dialogues and feelings that have the potential to violate patients' dignity or respect. Once the nurse identifies those internal feelings, he or she can do the hard work of trying to understand the origins of those feelings so that engagement with patients can grow ethically. This is particularly important in the context of religion and spirituality, as society tends to polarize over religious beliefs. If you are a "believer," do you judge harshly the "unbeliever"? If you are agnostic or atheist, do you dismiss the believer? Box 27-6 provides some questions that are useful for you to reflect on.

► BOX 27-6 Nursing Care Reflective Exercises

Take a few moments to reflect on the following questions:

- Do you believe that there is a God or ultimate authority in the universe? If so, how does that belief influence your behaviour, and ultimately your nursing care?
- How do you feel about religion? Should religious beliefs be accounted for in the context of nursing care?
- Why does suffering happen in the world? How should individuals respond to suffering?
- What behaviours in life do you consider immoral or wrong? What patients might you look after who would exhibit those behaviours and how might your beliefs influence your ability to give care?
- Do you come from a religious background and does that background encourage you to share your beliefs and possibly to convert others to those beliefs? How might that influence your practice? Should patients be allowed to try to convert you to their beliefs?
- What happens to you after you die?

Although these may seem like questions unrelated to nursing practice, understanding more about what you believe will help you to deal more authentically with the beliefs of others. It will also help you to think through issues that will ultimately arise in the context of your practice. It is also important to know that nursing practice itself might challenge you to rethink and reframe your beliefs. That is an important part of growing as a person.

In a recent study led by Canadian scholar Reimer-Kirkham, one of the key strategies of successful spiritual care was identifying points of commonality across diversity. Health care providers spoke of finding a human connection that transcended differing belief systems (Pesut & Reimer-Kirkham, 2010). This approach means identifying the common values that make people human and respecting the commitments and values that make humans unique. Love, trust, hope, forgiveness, meaning, and community are needs of all people.

Beyond a foundational approach of respect, there are two important ethical issues when nurses engage in spiritual care. The first is understanding and respecting appropriate nurse-patient boundaries. The second is ensuring that you are competent to engage in spiritual care and knowing when you are beyond your competency, so that you can refer to a spiritual care provider or social worker. Nursing is a relational process and so it is not always easy to discern where the professional boundaries lie. This is particularly relevant in spiritual care. When we establish a relationship with patients and we discern that they want to share the more intimate aspects of their spiritual lives with us, it is not always easy to know what is appropriate to do. Here is where questions arise, like the following:

- Is it appropriate to share my own beliefs with patients, particularly if they are different than theirs?
- Is there a role for proselytizing in nursing, or what do I do if patients try to proselytize me?
- Should I participate in religious practices like prayer if patients request it of me?
- How do I respond to what I perceive to be unhelpful spiritual beliefs (e.g., when individuals feel that they are being punished by God or resist health care treatment because they believe they will be divinely healed)?

The answers to these questions are complex and the responses will vary according to the context. This is why expert nursing judgement is so important. The *Code of Ethics for Registered Nurses* provides some important guidelines:

- Nurses provide care directed first and foremost toward the health and well-being of the person, family, or community in their care.
- Nurses respect the informed decision making of capable persons, including choice of lifestyles or treatment not conducive to good health.
- In health care decision making, in treatment, and in care, nurses work with persons receiving care, including families, groups, populations, and communities, to take into account their unique values, customs, and spiritual beliefs, as well as their social and economic circumstances.
- Nurses maintain appropriate professional boundaries and ensure their relationships are always for the benefit of the persons they serve.
- If nursing care is requested that is in conflict with the nurse's moral beliefs and values but in keeping with professional practice, the nurse provides safe, compassionate, competent, and ethical care until alternative care arrangements are in place to meet the person's needs or desires. (Canadian Nurses Association, 2008)

As you study these guidelines, you can see that there are some important principles to adopt in relation to boundaries and spiritual care. First, it is always the patient's best interest that should be foremost. In the case of sharing your own values and beliefs, the first question should be whose interests does this serve, yours or the patient's. Second, patients have a right to make decisions about their health care on the basis of spiritual and religious beliefs that we may not agree with. Our role is to inform them of the best evidence in relation to their decision. They have the right to choose. Third, as a nurse you, too, have the right to abstain from health care situations that violate your religious or spiritual beliefs, providing you ensure that alternative arrangements can be made. The following quotation, taken from a consensus report on spiritual care in palliative care, is an excellent statement on boundaries in the context of professional patient relationships:

The health care professional–patient relationship is often a one-way relationship that lacks equality and reciprocity. Boundaries allow for compassionate presence in the healing encounter. Health care professionals are more vulnerable to crossing these boundaries when they are overworked, stressed, or have experienced chronic losses or grief. Thus, it is critical that institutions and individual professionals make opportunities for appropriate self-care and reflection to avoid these risks. (Puchalski et al., 2009, p. 901)

The situations described above are just a few illustrations of how important it is to ensure that, as a nurse, you are competent to engage in spiritual care. Competencies for spiritual care include establishing therapeutic relationships, understanding the meanings of diverse spiritualities and their implications for care, and knowing when to refer to spiritual care providers (see Safety Alert). Although many nursing studies have suggested nurses feel ill-prepared to provide spiritual care, these studies often suggest that spiritual care is a discrete domain of care rather than an aspect of care that is embedded within the caring relationship in nursing. Thus, nurses are already well prepared to engage in the types of authentic and trusting relationships that provide a good context for spiritual care.

safety alert

One of the most important competencies for nurses is knowing when to refer to a spiritual care provider (we are using the term *spiritual care provider* to refer to both health care chaplains and spiritual leaders from the community who provide spiritual oversight to a group). Although nurses can provide a caring context for patients' spirituality, this should not in any way be misconstrued to suggest that nurses have expertise in spiritual care (unless they have additional education in this field). Part of excellent care is understanding when patients require expert assistance, either from a spiritual leader from their tradition or from a social worker if they do not adhere to a religious tradition (Pesut et al., 2009).

Fowler (2002), a nurse, theologian, and health care chaplain, has suggested that spiritual care has layers, somewhat like an onion. At the outermost layers are public and semipublic information that most individuals willingly share. However, as you peel the layers away, you encounter more intimate layers when individuals often struggle with troubling feelings, guilt, and concerns and encounter challenges that should be dealt with only by a trusted religious leader. Nurses are competent to deal with the more public layers and should be concerned about things such as the influence of their own tradition on health, healing, decision making, and beliefs about illness, suffering, and end of life. However, for a nurse to go beyond those layers to the deeper spiritual struggles is risky both for the nurse and the patient. Fowler likens it to a nonswimmer jumping in to save a drowning person. Nurses are not educated to address health related spiritual beliefs. If those beliefs are unhealthy (e.g., when individuals feel that God is punishing them), the nurse may not have the expertise to provide a reframing of those beliefs toward a more healthy outcome. Therefore, it is critical that nurses know who their referral persons are and be quick to refer if they sense that the spiritual struggles are beyond their expertise.

Sources: Fowler, M. (2002). *Spiritual care in nursing*. Course lectures in graduate course, Azusa Pacific University, Azusa, CA; and Pesut, B., Fowler, M., Reimer-Kirkham, S., Johnston Taylor, E., & Sawatzky, R. (2009). Particularizing spirituality in points of tension: Enriching the discourse. *Nursing Inquiry*, 16(4), 1–10.

However, what nurses are often less confident about is providing care across diverse religious and spiritual traditions. This is a valid concern in light of the risk for harm if we fail to take into account these beliefs. For example, taking off the sacred garb of a baptized Sikh has important religious implications. Although doing so is often unavoidable in health care, it requires sensitivity to the implications and assistance, if necessary, with reconnecting them with their religious community for restoration of their baptized state. This is just one of many examples of religious implications for care. Unfortunately, many of these situations have been downplayed in nursing recently because of the desire to recognize spirituality apart from religion and to not stereotype individuals within religious traditions. These are certainly valid concerns. However, it is possible both to recognize the validity of spirituality and religion and to understand the possible implications of religious traditions without stereotyping.

Table 27-1 provides *possible* care considerations for some of the most common religious traditions encountered. These considerations will become even more important as Canadian society becomes increasingly diverse. Naturally, it is important to remember that this is just a starting point. This allows nurses to enter the caregiving situation with some background knowledge but is essential to clarify with each individual the practices they adhere to within their tradition. There is great variability even among common religions, and individuals will pick and choose the practices they adhere to within that religion. You need not be afraid to ask. Many religious individuals will gladly talk about their faith and practices if you are open.

► **TABLE 27-1 Religious Beliefs About Health**

Religious or Cultural Background	Possible Health Care Beliefs and Practices	Nursing Implications
Hinduism	Modern medical science is accepted. Illness is caused by past sins. Holy days are celebrated with fasting, prayer, and feasting.	Privacy is needed for prayer and meditation. Modesty in clothing is important, and hospital gowns may be considered indecent; same-sex caregivers are preferred. Important sacraments are associated with birth, naming, puberty, and death. Religious symbols should not be removed. Prayers are said twice a day; privacy is preferred. Modesty in clothing is important, and hospital gowns may be considered indecent; same-sex caregivers are preferred. Religious symbols include uncut hair, comb, steel bracelet, symbolic dagger, undershorts, and turban; these should not be removed. Cleanliness during eating and prayers is important.
Sikhism	Modern medical science is accepted. Baptized and nonbaptized Sikhs have different religious requirements.	Treatment may be refused on holy days. Prayers usually occur five times daily. Privacy is needed for meditation. The patient may want a Buddhist monk in attendance for spiritual support.
Buddhism	Modern medical science is accepted. Understanding, rather than belief, is emphasized. Dharma, the law of nature, teaches that life is impermanent and all people have to age and die. Death is usually accepted as the last stage of life, and withdrawal of life support may be permitted. Buddhists may believe in rebirth after death.	
Islam	Muslims must be able to practise the Five Pillars of Islam. Muslims may have a fatalistic view of health. Faith healing is used. Withdrawal of life support may be permitted. Autopsies are generally forbidden.	Prayers are said five times per day, facing toward Mecca. Privacy is important. Fasting may occur on holy days. Modesty in clothing is important, and hospital gowns are considered indecent; same-sex caregivers are required.
Judaism	Jews believe in the sanctity of life. God and medicine must have a balance. Observance of the Sabbath is important.	Prayers are said three times per day; men may wear prayer shawl and skull cap. Treatment may be refused on the Sabbath.
Christianity	Modern medical science is accepted. Many Christians follow complementary alternative medicine (see Chapter 34). Prayer and faith healing are used; some Christians use laying on of hands.	Times of prayer vary between individuals; privacy is preferred. Sacraments of Holy Communion and the Anointing of the Sick may be practised. Religious symbols may include cross and prayer beads.
Hutterites	Modern science is accepted. About 80% of Hutterites seek alternative therapies. All things are shared communally. Hutterites live on colonies to help avoid earthly distractions that impede spiritual practice and devotion. Praying for good health is not appropriate; rather, prayers may be for wisdom to live a healthy life or bear suffering without complaint. Created order is God over man, man above woman, elder adult above younger adult, and parent over child.	Education about health is appreciated. Straightforward discussions are preferred. Health providers are respected. Families expect to be involved in health care discussions. Decision-making processes about what health concerns are important for the colony are made by the leaders.
Ojibway (Anishinabe)	Central value is that everything belongs to everyone in extended family. Health is a spiritual experience. Disease and illness may be caused by soul loss or spiritual intrusion.	Individual decisions regarding medical treatment may be made in consultation with other members of the colony. Families generally want to be involved in health care decisions and may wish to stay with the ill individual. They desire to get to know the nurse before sharing problems. They may use Western medicine blended with traditional healing practices.

Providing Spiritual Care

Spiritual care is often overlooked in the provision of nursing care (Burkhart & Hogan, 2008; Creel, 2007; et al., 2007; Pesut & Reimer-Kirkham, 2009). Some perceived barriers to nurses offering spiritual care are perceived time constraint, lack of knowledge of the issues, lack of confidence in opening and holding spiritual conversations, challenges in articulating spirituality, uncertainty as to what spiritual care entails, and the multiplicity of beliefs, ideologies, religions, philosophies, and creeds (Hood et al., 2007). Sawatzky and Pesut (2005) caution that lack of attention to spiritual needs may cause people to abandon the traditional health care system and prevent them from drawing on inner resources for health and healing.

Spiritual nursing care, at its foundation, is an expression of self (Sawatzky & Pesut, 2005). To engage in spiritual care, you must first be comfortable with hearing about patients' spirituality. **Spiritual care** is an altruistic, relational, intuitive, and integrative process by which you seek to understand and reflect the patient's spiritual values, beliefs, and experiences (Figure 27-2; Sawatzky & Pesut, 2005): altruistic in that it requires that the nurse put the patient's need first; relational in that patients feel their spirituality is supported through an interpersonal relationship of care; intuitive in that the mysterious nature of spirituality cannot always be understood through rational thought; and finally, integrative in that spirituality should not be considered separate from the other aspects of care. The relief of suffering through excellent pain management contributes to spiritual well-being because persons are holistic.

Relational practice is a process of respectful, compassionate, and authentic inquiry into the experience of another (Doane &

Varcoe, 2005). Many of the relational capacities taught throughout nursing curricula offer support to nurses as they provide nursing care that includes the patient's spirituality (Box 27-7). The relational skills that undergird all of nursing practice are the same skills that create the foundation of spiritual care. Recognizing this may help offset feelings of inadequacy that arise when nurses think about providing spiritual care (Pesut, 2008b). According to Sawatzky and Pesut (2005), "Spiritual expressions such as love, hope and compassion constitute the most basic and universal approach to spiritual care and can be integrated into all aspects of nursing care" (p. 23). In research involving 156 cancer patients and 68 family caregivers, relationship, genuine kindness, and respect were the foundational requests of patients before receiving spiritual care (Johnston Taylor, 2007a).

Nurses grow in their ability to provide spiritual care. Expert spiritual caregivers state that "their knowledge base was acquired through the relationships that they enjoyed with patients, family, and peers" (Belcher & Griffiths, 2005, p. 275). The beginning point of spiritual care is presence and formation of relationship and a willingness to enter into conversations about what is meaningful and important to each patient. A nurse is called to transcend the tendency to generalize and

FOCUS ON PRIMARY HEALTH CARE

Learning to Care for Spiritual Needs

One of the most important aspects of primary care is the relationship established between health care providers and patients. In this study, Canadian nurses Hood, Olson and Allen (2007) explored how practising nurses learned to care for spiritual needs. They interviewed 15 nurses ranging in age from 25 to 64 years and with 2 to 43 years of professional experience. They suggested that learning to connect was the basic social process that defined how spiritual care occurred. Connection had living, needing, nurturing, and learning elements. Participants shared that living connection was a way of being spiritual in the world that was guided by universal spiritual principles. Both patients and nurses often realized their need for connection through difficult experiences they encountered. Nurturing connection included being fully present, attending to the needs of patients, and engaging in therapeutic relationships. Finally, learning connections often entailed a process of observing, reflecting on, and testing experiences of spiritual care.

Another Canadian study led by Reimer-Kirkham, Pesut, Meyerhoff, and Sawatzky (2010) looked at the negotiation of religious and spiritual plurality in clinical health care encounters. Connecting in clinical encounters occurred in various ways. Eliciting patients' meaning systems was an important strategy for connecting. Sometimes connections occurred because of a shared religious or spiritual identity, but in other cases, connections occurred across different religious traditions as individuals showed respect and sought for common ground. Something as simple as giving physical care or eating food could be a deeply spiritually meaningful shared experience.

make assumptions to find what truly nurtures each patient's unique spirituality. Acknowledging that the nurse does not have to be the expert in spirituality can relieve the anxiety experienced by nurses in providing spiritual care.

Facilitating Spiritual Practices

Rituals that bring meaning to life are spiritual practices. Many spiritual practices are integrated throughout a person's daily activities and do not necessarily take place in a church or formal setting. What is considered spiritual practice varies greatly from person to person, even for people of the same spiritual or religious tradition. These may be as varied as practices or sacraments associated with a person's religion, such as prayer, daily readings, or communion, and informal practices, such as enjoying a sense of connectedness with others or enjoying the beauty of nature (see Box 27-8 for examples of spiritual practices). Demystifying spiritual practice and recognizing those places in everyday life where spiritual practices are present, but not identified as such, creates awareness.

Consider for a moment the things that bring greatest meaning to your life, the times when you feel peace, you feel joy, you feel purpose. What were you doing right before you experienced those feelings? Did you pause for a moment and take a breath? Did you recognize the beauty of the garden outside your window? Did you feel gratitude for the meal before you? Did you recognize the humanity in a face before you? These are all spiritual practices and can be nurtured and grown once they are brought to awareness. Through this awareness, one can choose to consciously connect and be fully present in the moment. Being fully present in the moment, or "presence," facilitates spiritual care (Swinton & Pattison, 2010). It is important to nurture this awareness since nurses who have a spiritual base or identity are more likely to facilitate

spiritual practices and provide spiritual care in practice (Cavendish et. al, 2004; Chan, 2010).

Food and nutrition are important aspects of patient care and often an important component of some religious observances. Food and the rituals surrounding the preparation and serving of food can be important to a person's spirituality. You can consult with a dietitian to integrate the patient's dietary preferences into daily care. In the event that an agency cannot prepare food in the preferred way, the family may be asked to bring meals that accommodate dietary restrictions. Personal care of the patient should be planned to allow time for religious readings, visits by spiritual advisors, or attendance at religious services. Some churches and synagogues offer audiotapes of their services for those members who cannot attend in person. Family members can plan a prayer session or an organized reading of religious material on a regular basis. Arrangements may need to be made with spiritual care staff for the patient and family to receive the sacraments. Clergy will routinely offer to make home visits for people unable to attend religious services. Taped meditations, classical or religious music, and televised religious services are other options. You should be respectful of icons, medals, prayer rugs, or crosses that patients bring to a health setting; be sure that they are not accidentally lost, damaged, or misplaced (see Nursing Story, Box 27-9).

Reflecting on Nurses' Spiritual Care

Growing along the journey of spirituality is a lifelong pursuit, and one that is not easily evaluated by others. Particularly during times of illness and suffering, patients need to clarify values, to reshape philosophies, to strengthen relationships, and to live experiences that help to shape their purpose in life. We propose that it is not normally within the nursing role to "evaluate" whether patients achieve connectedness, meaning, peace, hope, or other indicators of spirituality. Meaning making during suffering is often a mysterious, highly personal experience as illustrated by the following story. Job is character in a Christian story about suffering. Job comes to a period in his life of enormous suffering when he loses his wealth, his family, and ultimately his health. As he struggles to find meaning in his suffering, his friends come to visit and sit with him. They

BOX 27-9 NURSING STORY

The meaning held in a simple act of respect for a patient's important religious symbol was taught to me by two first-year nursing students. On a busy morning in residential care, Maria,* an elderly female resident, was distracted and anxious because the religious medals that she always wore next to her heart were missing. The two students found out from the staff that the medals had been missing for several days, and they were advised to simply get the patient dressed and to the dining room. The students, understanding the sense of peace these medals brought to Maria, became determined to find them. They did indeed find the medals. As they returned the medals to their special place next to Maria's heart, her affect turned from worry to joy. Maria was transformed by the caring actions of the students. In the weeks that followed, Maria's face lit up when these students came into her room. With this simple act, the students had provided the spiritual care that was needed in the moment.

EVIDENCE-INFORMED
PRACTICE GUIDELINE**The “Little Extra” That Alleviates Suffering**

What is the ethical ideal of nursing care that reduces suffering? That is the question asked by some Swedish nurses. They engaged in a Socratic dialogue with six experienced nurses and four nursing students in their last year of undergraduate study. A Socratic dialogue entails a mutual discussion aimed at allowing participants to explain their ethical outlook on life. In addition, they interviewed two cancer patients.

The experienced nurses believed that “ideal care means seeing the whole person, giving them respect and acting accordingly: being able to see the person delivers the caring acts. Evidence of this can be seen in the carers’ willingness to give the little extra” (p. 376).

The nursing students believed that “ideal care means acknowledging and being touched by the other person’s situation as a fellow being. Evidence of this is extra commitment to individuals and acting according to their needs” (p. 377).

The patients suggested it is the “power or magic in genuine commitment and interest. You are a person not a diagnosis” (p. 377).

The authors concluded that ideal nursing care goes beyond—to give that little extra. This willingness and ability often arise from the caregiver’s own progression in the understanding of life, which allows them to open up to the patient’s suffering and vulnerability. Ultimately, they conclude that it is often the small acts that preserve patient dignity because patients feel cared for and valued.

Those little extras are an important part of spiritual care.

Source: Arman, M., & Rehnsfeldt, A. (2007). The “little extra” that alleviates suffering. *Nursing Ethics*, 14(3), 372–386.

mean well, but as they sit and observe his plight, it becomes too much for them. Each of them tries to understand the meaning of his suffering so that they can make it right for him. They propose all kinds of causes for his suffering and ways that he can make it better. But their good intentions only cause him further distress. Ultimately, he never finds answers to his plight but finds great comfort in God.

As nurses, we can take some important guidance from this story. We can always be present for patients in their suffering, and certainly we can do everything within our power to alleviate distress (see Box 27-10). We should aggressively treat pain and other symptoms. We should provide a hospitable climate for those who are most important in patients’ lives. We should put great effort into ensuring that patients can continue with their religious and spiritual practices. We should know the values and beliefs that are important to take into account as part of the overall picture of care. These are all spiritual “interventions.” But we need to be cautious about entering into the areas of mystery, particularly if we are sensing our own need to explain or control patients’ suffering.

In this aspect of nursing care, it is more appropriate to reflect on your own contributions to a healing relationship. Were patients’ spiritual practices respected? Was the relationship characterized by caring and support? Does the patient express trust and confidence in you? Is the patient able to discuss important issues or topics? Is the patient comfortable expressing spiritual needs to you? That sense of rapport that develops within a nurse–patient relationship is often the best

indicator that you have helped to provide a safe context within which patients can live their spiritual journey.

✦ **KEY CONCEPTS**

- Spirituality is highly personal and unique to each individual.
- Nurses must be aware of their own spirituality in order to recognize the spirituality of others.
- Canadian nursing practice has a rich spiritual heritage that has influenced contemporary practice.
- Spirituality may have beneficial health outcomes.
- Body, mind, and spirit are interconnected; thoughts, expectations, and beliefs may affect physical well-being.
- Nursing theories can guide nurses in providing spiritual care.
- Faith is a relationship with God or a higher power or authority that enables action and gives purpose and meaning to an individual’s life.
- Religion is a system of organized beliefs and worship that a person practises to express spirituality outwardly.
- Spirituality is a lifelong journey that may reflect the age and life experiences of the patient, as well as their current context.
- When patients experience acute or chronic illness or a terminal disease, spiritual resources either help a person recover or spiritual concerns develop.
- Spiritual practices are varied and may include private worship, prayer, meditation, sacraments, singing, use of rosary or prayer beads, and reading religious texts.
- Critical thinking in spiritual care includes an understanding of the unique perspective of the patient.
- A spiritual assessment is most successful when nurses attempt to understand rather than assess patients’ spirituality, allowing the development of the relationship.
- Spiritual assessment tools should be flexible, and the depth of the assessment must be sensitive to the circumstances.
- The personal nature of spirituality requires open communication and the establishment of trust between nurse and patient.
- Certain religions may have dietary restrictions or beliefs and practices of health care that may have implications for nursing practice.
- Spiritual practices may be an effective coping resource for physical and psychological symptoms.
- Providing spiritual care may result in an increased or restored sense of connectedness with significant others and maintaining, renewing, or reforming a sense of purpose in life.

✦ **CRITICAL THINKING EXERCISES**

1. Mr. Gadacz is a 40-year-old businessman with more than 100 employees. A 12-hour workday is not unusual for him. He is married, has four teenage children, and is solely responsible for providing financially for the family. Last evening, he was admitted to the cardiac care unit with severe chest pain resulting from a myocardial infarction (heart attack). He is now stabilized but frequently asks about his diagnostic tests and what he needs to do to be able to go home. He tells his nurse, “My doctor tells me I will need surgery once I am more stable. I hope he can do that soon. I just can’t believe this is happening. I worry about what will happen to my business while I am gone and to my family if I can’t keep my business going.” He asks you, “Could I die from this?” You notice that Mr. Gadacz has devotional literature at his bedside. How might you go about conducting a spiritual health assessment for Mr. Gadacz?
2. Tejal is a new graduate nurse caring for Ms. Rosenbaum for the first time. Ms. Rosenbaum is 27 years old and has recently received a diagnosis of uterine cancer. She is scheduled for

an abdominal hysterectomy. Tejal notices from the patient chart that Ms. Rosenbaum has identified herself as Jewish. What factors might be important to consider in relation to Ms. Rosenbaum's spirituality or religion for the plan of care? How might Tejal determine which factors are relevant for Ms. Rosenbaum?

3. Critical thinking is an ongoing process. When you learn that you are assigned to care for Fangzhou Lin, you note that the Kardex information includes his religion (Buddhist) and his place of birth (Hong Kong). A colleague tells you he can speak some English. The patient is 80 years old and reportedly has a hearing deficit. What knowledge might you wish to reflect on critically before beginning a spiritual assessment of this patient?

✦ REVIEW QUESTIONS

1. Caring for a patient's spiritual needs means
 1. Having the same beliefs as the patient
 2. Praying for the patient
 3. Accepting the patient's beliefs and experiences
 4. Calling for a religious leader if you determine a need
2. An individual who does not believe in the existence of God is an
 1. Agnostic
 2. Atheist
 3. Anarchist
 4. Agenic
3. Patients' rituals and practice
 1. Have no place in modern medicine
 2. Have no place in the hospital
 3. Can get in the way of nursing care
 4. Provide structure and support for the patient
4. Establishing presence is not simply being in the same room with a patient; it also involves
 1. Offering a closeness with the patient: physically, psychologically, and spiritually
 2. Performing procedures
 3. Touching the patient
 4. Sharing your own beliefs as a way to bring comfort
5. For those adhering to the Hindu religion, it is important to consider that
 1. Modern medical practice is not accepted
 2. Followers may observe fast days
 3. Opposite sex caregivers are permitted
 4. Removing religious symbols is permissible
6. Spirituality is
 1. A structured search for God
 2. Completely different than religion
 3. An appropriate term to use to describe atheists
 4. Commonly identified with meaning, purpose, hope, and connectedness
7. Research has shown that patients appreciate all of the following from the nurse, *except*
 1. Intimate interventions such as meditation or journaling
 2. Supporting personal spiritual interventions
 3. Doing the little "extras"
 4. Knowing about their spirituality and spiritual concerns

8. Patients who experience terminal illness or who have suffered a recent disability because of a disease or injury can benefit from
 1. Grief work
 2. Diet therapy
 3. Acupuncture
 4. Values clarification
9. Spiritual assessment
 1. Should be structured and follow specific process
 2. Is not required or recommended
 3. Is the first component of the nursing process
 4. Should be flexible and the depth of the assessment must be sensitive to the circumstances
10. Relational practice
 1. Causes tension between the nurse and the patient if they hold conflicting beliefs
 2. Creates the environment for spiritual care
 3. Allows nurses to establish clear boundaries
 4. Is not a component of spiritual care

The Experience of Loss, Death, and Grief

Original chapter by Valerie Yancey, RN, PhD

Canadian content written by Jim Hunter, RN, MSN

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Identify your role in assisting patients who have experienced loss, death, and grief.
- Describe and compare the phases of grieving from Kübler-Ross (1969), Bowlby (1980), and Worden (1991).
- List and discuss the five categories of loss.
- Describe the types of grief.
- Describe the characteristics of a person experiencing grief.
- Discuss variables that influence a person's response to grief.
- Develop a nursing care plan for a patient or family experiencing loss and grief.
- Explain reasons for the need for improved end-of-life care for patients.
- Discuss principles of palliative care.
- Describe how to involve family members in palliative care.
- Describe the procedure for care of the body after death.
- Discuss your own loss experience when caring for dying patients.

Loss and grief are experiences that affect not only patients and their families, but the nurses who care for them as well. In Canada and other Western societies, palliative and end-of-life care continues to develop its role in health care and gain acceptance, despite barriers that include a focus on the more dominant medical model, where the focus is on cure (Melvin & Oldham, 2009). As a result, Canadians often deny death, as well as the need to express grief and to feel the pain associated with a loss, both of which are beneficial to healing. Grief affects survivors physically, psychologically, socially, and spiritually as a result of very real concrete and perceived losses. Death of a patient, for example, leaves family, friends, and caregivers feeling powerless. Most nurses enter the profession with the intent of helping patients recover from illness, adjust to illness-related changes in lifestyle, and move toward health restoration. It is often frightening to learn that knowledge, skill, and technology do not always result in cure.

Your role in facilitating the grief process includes assisting survivors to feel the loss, express the loss, and complete the stages of the grief process. To be effective, you must have a thorough understanding of a patient's loss, its significance and meaning to the patient and family, and how it affects the patient and family's ability to carry on. Providing care for patients in crisis from loss or during the end of life requires knowledge, caring, and compassion to help bring comfort to patients and families, even when hope for a cure is gone. Helping patients to a peaceful, dignified death is an important aspect of your nursing care. Although working with dying patients can be challenging, many nurses also find it to be a rewarding and often life-changing experience, both professionally and personally (Chochinov, 2006).

Scientific Knowledge Base

Loss

Throughout their lives, people form attachments and suffer losses. They develop independence from their parents, start and leave school, change friends, begin careers, and form relationships. The growing-up process is natural and positive, and yet as people's lives unfold, they suffer necessary losses (Hasler, 1996). **Necessary losses** are an integral part of each person's life. People expect their losses to be recovered and replaced by something different or better, but other losses cause an unbearable change in their sense of safety and security (Hasler, 1996). Losses such as the death of a loved one, divorce, or loss of independence are significant and can have long-term effects on physical and psychological health. Loss comes in many forms, depending on the values and priorities learned within a person's sphere of influence, made up of family, friends, society, and culture. A person experiences loss in the absence of an object, person, body part or function, emotion, or idea that was formerly present (Table 28-1). Losses may be actual or perceived. An **actual loss** is any loss of a person or object that can no longer be felt, heard, known, or experienced by the individual. Examples are the loss of a body part, a child, a relationship, or a role at work. Lost objects that have been valued by a patient could be any possession that is worn out, misplaced, stolen, or ruined. For example, a child may grieve over the loss of a favourite toy. A **perceived loss** is any loss that is defined uniquely by the grieving patient. It may be less obvious to others. An example is the loss of confidence or prestige. Perceived losses are easily overlooked or misunderstood, and yet the process of grief follows the same sequence and progression as that for actual losses. Individual interpretation makes a difference in how the perceived loss is uniquely valued and the response that a person will have during grieving.

Losses may also be maturational, situational, or both. A **maturational loss** is any change in the developmental process that is normally expected during a lifetime. One example would be a parent's feeling of loss as a child goes to school for the first time. Events associated with maturational loss are part of normal life transitions, but the feelings of loss persist as grieving helps a person cope with the change. **Situational loss** is any sudden, unpredictable external event. Often this type of loss includes multiple losses rather than a single loss; for example, an automobile accident may leave a driver paralyzed, unable to return to work, and grieving over the death of a passenger in the accident.

The type of loss and the perception of the loss influence the depth and duration of grief that a person experiences. Each

► TABLE 28-1 Types of Loss

Definition	Implications of Loss
Loss of external objects (e.g., loss, misplacement, deterioration, theft, destruction by natural causes)	Extent of grieving depends on object's value, sentiment attached to it, and its usefulness.
Loss of known environment (e.g., moving from a neighbourhood, hospitalization, leaving or losing a job, moving out of intensive care unit)	Loss occurs through maturational or situational events and through injury or illness. Loneliness or newness of an unfamiliar setting threatens self-esteem and makes grieving difficult.
Loss of a significant other (e.g., through being promoted, moving, or running away; loss of a family member, friend, trusted nurse, acquaintance, or animal companion)	Significant other typically fulfills another person's need for psychological safety, love and belonging, and self-esteem.
Loss of an aspect of self (e.g., body part, psychological function, or physiological function)	Illness, injury, and developmental changes result in loss of aspect of self that causes grief and permanent changes in body image and self-concept.
Loss of life (e.g., death of family members, friend, or acquaintance; own death)	Loss of life creates grief for the survivors. The person facing death often fears pain, loss of control, and dependency on others.

individual responds to loss differently. It is incorrect to assume that the loss of an object does not generate the same level of grieving as the loss of a loved one. The value an individual places on the lost object (e.g., a family heirloom) determines the emotional response to the loss. You must assess the special meaning that a loss has for a patient and validate its effect on the patient's health and well-being.

Hospitalization, chronic illness, and disability are special circumstances that are associated with multiple losses. When patients enter a hospital, they lose their privacy, control over their daily routines, and any illusions that they may have about their personal indestructibility. In addition, modesty and control over bodily functions may be compromised. A chronic illness or disability often engenders concern over financial security. Furthermore, long-term illness may necessitate a job change, threaten independence, and force alterations in lifestyle. Even a brief illness or hospitalization necessitates temporary shifts in family role functioning. Chronic or debilitating illness may pose a major threat to the stability of relationships.

Death is the ultimate loss. Although death is part of the continuum of life and a universal and inevitable part of being human, it is also a mystical event that generates anxiety and fear. Death ends relationships and separates people. Even with a strong spiritual grounding, facing death is often difficult for the dying person, as well as for the person's family, friends, and caregivers. A person's terminal illness reminds close

friends and associates of their own mortality. A person with an advanced, progressive, ultimately fatal illness, such as chronic renal failure, end-stage heart failure, amyotrophic lateral sclerosis, or metastatic cancer, faces many—often progressive—levels of suffering. It is difficult to be sick, and many people dislike seeking help from others; however, nearly all want companionship and want to strengthen relationships with significant others when death is imminent (Chochinov, 2006).

When faced with death, feelings of guilt, anger, and fear arise. It may cause family members and caregivers to withdraw at a time when the dying person needs a trusted, unhurried companion, acting with gentle advocacy and humility. Patients faced with death are increasingly choosing to die at home (National Consensus Project [NCP], 2009); as a result, family members are becoming more involved in the care of their loved one. The way a person approaches dying is influenced by personal fundamental beliefs and values, past experiences with death, culture, spirituality, and the quality of the human emotional support available.

Grief

Grief is the emotional response to a loss or death (Waldrop, 2007). Each individual responds to loss differently, grieving at an individual pace and pattern (Corless, 2010). Differences are based on individual experience, previously established coping strategies, cultural expectations, and spiritual beliefs (see Chapters 9 and 27) and involve the process of mourning and the process of adapting to a loss (Waldrop, 2007). It involves working through the grief until an individual accepts and adapts to his or her expectations to find meaning in the loss, and to go on in life without that which was lost (Corless, 2010).

Bereavement includes grief and mourning; it is the state of having lost a significant other to death (Waldrop, 2007). Survivors go through a bereavement period that is not linear. It does not proceed in sequential stages that can be precisely predicted, which may imply passivity on the part of the bereaved person. Rather, a survivor will move back and forth through a series of stages, tasks, or both many times, possibly over a period of several years, before the process is completed. Although no one really “gets over” a loss, the individual can heal and adapt to the loss. A useful analogy is to think of a new ring on a finger. Initially, the wearer is always aware that it is there, but over time, it will be less noticeable and yet still present. Several theorists have formulated stages of the grieving process as a series of tasks for survivors to work through their bereavement and adapt to life with a loss.

Selected Theories of Grief

Kübler-Ross's Stages of Grief. The framework for Kübler-Ross's (1969) theory is behaviour oriented and has five stages (Table 28-2). During **denial**, an individual acts as though nothing has happened and may refuse to believe or understand that a loss has occurred. In the **anger** stage, the individual resists the loss and may strike out at everyone and everything. During **bargaining**, the individual postpones awareness of the reality of the loss and may try to deal in a subtle or overt way as though the loss can be prevented. A person finally realizes the full impact and significance of the loss during the stage of **depression**, when the individual may feel overwhelmingly lonely and withdraw from interpersonal interaction. Finally, during the **acceptance** stage, the individual accepts the loss and begins to look to the future. Although these stages are valuable for novice nurses to understand the grief process, stage or phase theories may be seen as having

► TABLE 28-2 The Grief Process

Kübler-Ross's (1969) Five Stages of Grief	Bowlby's (1980) Four Phases of Mourning	Worden's (1991) Four Tasks of Mourning
Denial	Numbing	Accepting the reality of loss
Anger	Yearning and searching	Working through the pain of grief
Bargaining	Disorganization and despair	Adjusting to the environment without the deceased
Depression	Reorganization	Emotionally relocating the deceased and moving on with life
Acceptance		

limitations in some situations, because in reality, the stages and phases of grief may occur nonsequentially or may overlap (Buglass, 2010).

Bowlby's Phases of Mourning. Bowlby's (1980) attachment theory is the foundation for his theory on mourning. Attachment is described as an instinctive behaviour that leads to the development of affectionate bonds between children and their primary caregiver. These bonds are present and active throughout the life cycle. Later, the bonds are generalized to other people with whom individuals form close relationships. Attachment behaviour ensures human survival because it keeps people in close contact with other people who can offer protection and support.

Bowlby (1980) described four phases of mourning (see Table 28-2). As in the case of the other grief theories, a person can move back and forth between any two of the phases while responding to the loss. The **numbing** phase may last from a few hours to a week or more and may be interrupted by periods of extremely intense emotion. It is the briefest phase of mourning. The grieving person may describe this phase as feeling “stunned” or “unreal.” Numbing may serve to protect the body from the onslaught or consequence of the loss. The second phase of **yearning and searching** arouses emotional outbursts of tearful sobbing and acute distress in most people. Corless (2010) describes how it is necessary for the bereaved person to experience the pain of grief in order to finish the work of grief, through finding meaning in the loss. Therefore, anything that continually allows the person to avoid or suppress the pain can be expected to prolong the course of mourning. Common physical symptoms are tightness in the chest and throat, a shortness of breath, feelings of weakness and lethargy, insomnia, and loss of appetite. A person may also experience an intense yearning for the object or individual who is lost. This phase may last for months or years. During the phase of **disorganization and despair**, an individual may constantly examine how and why the loss occurred. It is common for the person to express anger at anyone who might be responsible. This examination gradually gives way to an acceptance that the loss is permanent. During the final phase of **reorganization**, which may require as much as a year or more, the person begins to accept unaccustomed roles, acquire new skills, and build new relationships. People experiencing

this phase must be encouraged to find meaning and hope in their loss, without lessening its importance (Corless, 2010).

Worden's Four Tasks of Mourning. Worden's (1991) four tasks of mourning imply that people who mourn can be actively involved in helping themselves and can be assisted by outside intervention. Although time varies greatly among individuals, working through the tasks typically requires a minimum of a full year.

- *Task 1: To accept the reality of the loss.* Even when a death has been expected, some period of disbelief and surprise that the event has really happened always occurs. This task involves the processes required to accept that the person or object is gone and will not return.
- *Task 2: To work through the pain of grief.* Even though people respond to loss differently, it is impossible to experience a loss and work through grief without emotional pain. Individuals who deny or shut off the pain prolong their grief.
- *Task 3: To adjust to the environment in which the deceased is missing.* According to Worden (1991), a person does not realize the full impact of a loss for at least three months. At this point, many friends and associates make less frequent contact, and the person is left to ponder the full impact of loneliness. People completing this task must take on roles formerly filled by the deceased, including some tasks that they never fully appreciated.
- *Task 4: To emotionally relocate the deceased and move on with life.* The goal of this task is not to forget the deceased or give up the relationship with the deceased but to have the deceased take a new, less prominent place in a person's emotional life. This is often the most difficult task to complete because people fear that if they make other attachments, they will forget their loved one or be disloyal. A person completes this stage after realizing it is possible to love other people without loving the deceased less.

Types of Grief. Knowledge of types of grief, which are based on characteristics or signs and symptoms of grief, enables you to implement appropriate bereavement therapies.

Normal Grief. Normal or uncomplicated grief consists of the normal feelings, behaviours, and reactions to a loss, including resentment, sorrow, anger, crying, loneliness, and temporary withdrawal from activities. Often the "healthy" grief response to a loss can prove positive, helping an individual mature and develop as a person as he or she comes to terms with the changes that have occurred in his or her life and works to rearrange and reorganize internal models (Grassi, 2007). This results in the development of adaptive coping strategies on which the person can rely in the future.

Anticipatory Grief. The process of disengaging, or "letting go," that occurs before an actual loss or death has occurred is called **anticipatory grief**. For example, once a person or family receives a terminal diagnosis, they begin the process of saying goodbye and completing life affairs. The process becomes more stressful when the patient is unable to make decisions as a result of the progression of illness. Unless guided by a patient's explicit decisions regarding end-of-life care, the family, in consultation with health care providers, assumes the responsibility of deciding whether to continue life-sustaining measures. The family must weigh factors such as the patient's known values and choices, the medical facts, opinions and probabilities, the burden of treatment, the expected future quality of life for the patient, and the limitations of their own emotional resources (Radwany et al., 2009).

When dying takes a long time, the patient's loved ones may exhibit few symptoms of grief once the death occurs. This seeming absence of grief symptoms may result because the family has engaged in the grief process over time. By the time the moment of death arrives, much of the shock, denial, and tearfulness have already been experienced.

Anticipatory grieving entails some risks. Family members may withdraw emotionally from the patient too soon, leaving the patient with no emotional support as death approaches. Complications may also arise if a person who was thought to be near death survives. Family members may then have difficulty reconnecting and may even be resentful that the person has lived past life expectancy.

Complicated Grief. When a person has difficulty progressing through the normal (generally accepted) phases or stages of grieving, bereavement becomes complicated. In these cases, bereavement appears to "go wrong" and loss has not been adequately dealt with. This can threaten a person's relationships with others. Complicated grief includes these four types:

- *Chronic grief:* Active acute mourning characterized by normal grief reactions that do not subside and continue over very long periods and that becomes complicated mourning (Worden, 2009). Affected people verbalize an inability to "get past" the grief. This may also be known as unresolved grief, or complicated grief. Coping strategies implemented during complicated grief tend to be maladaptive (Worden, 2009).
- *Delayed grief:* Characterized by normal grief reactions that are suppressed or postponed and by the survivor's conscious or unconscious avoidance of the pain of the loss (Worden, 2009). Active grieving is held back, only to resurface later, usually in response to a trivial loss or upset. For example, a wife may appear to grieve for only a few weeks after the death of her spouse, but then she may become distraught and sad when a minor event triggers emotion. The extreme sadness is a delayed response to the death of her husband. Multiple losses can cause the grieving to be delayed (Worden, 2009).
- *Exaggerated grief:* Grief that overwhelms people to the point that they cannot function. This may be reflected in the form of severe phobias or self-destructive behaviour such as alcoholism, substance abuse, or suicide.
- *Masked grief:* Lack of awareness by survivors that behaviours that interfere with normal functioning are a result of their loss. For example, a person who is grieving may exhibit physical or psychiatric symptoms; some people have been known to exhibit delinquent behaviours (Worden, 2009).

Disenfranchised Grief. People experience grief when a loss is experienced and cannot always be openly acknowledged, socially sanctioned, or publicly shared due to stigmatization (Worden, 2009). Examples are the loss of a partner from acquired immunodeficiency syndrome (AIDS), the loss of a child in utero or at birth, or the loss of a family member through suicide.

Application of Grief Theory to Other Types of Loss. Although grief theories apply mainly to the way that individuals cope with the death of a loved one, they also apply to other losses. The theories are relevant to the way people respond to a loss of body function, as in the case of organ transplantation or heart attack, and to disability, such as amputation of a limb or paralysis. Grief theory applies to individuals who progress through stages of mourning for lost

independence, body integrity, and a change in body image. These individuals experience genuine emotional pain as they progress through the stages of grieving.

Nursing Knowledge Base

Nursing knowledge has traditionally focused on the acute care setting, in which losses are more physical in nature. As you enter home and community settings, the definitions of loss are more comprehensive and in many ways different. You must develop interventions for each unique patient situation.

Factors Influencing Loss and Grief

The way that an individual perceives a loss and responds to it during bereavement is influenced by many factors.

Human Development. People of differing ages and stages of development display different and unique symptoms of grief. For example, toddlers are unable to understand loss or death, but they feel great anxiety over the loss of objects and separation from parents. School-aged children experience grief over the loss of a body part or function. They often associate misdeeds with causing death. Middle-aged adults usually begin to re-examine life and are sensitive to their own physical changes. Older adults often experience anticipatory grief because of aging and the possible loss of self-care abilities. Aging is frequently associated with losses such as physical changes, loss of employment, loss of social respect, loss of relationships, and threats to a sense of fulfillment and contributions made in life. Older adults are often resilient in responding to grief, despite its being a highly stressful process (Box 28-1); however they are also more likely to experience dysfunctional grieving (Worden, 2009).

Psychosocial Perspectives of Loss and Grief. Loss and death are life experiences that each person faces. Death is an overwhelming experience that affects everyone involved in the loss situation or in the death of the individual. Culture can

have a significant influence on people's views of death and how the dying should be cared for. In each culture is a set of beliefs and values that are the result of positive and negative experiences, cultural influences, and spiritual beliefs (Verosky, 2006). You are part of that same psychosocial environment and share many of the biases or perspectives gained during sociological development. Norms for psychosocial patterns of loss and grief are reflected in caregivers as well as in patients. You need to be aware of your own personal perspectives that may influence your approach and attitudes in caring for dying patients and their families (Verosky, 2006).

An individual's expression of grief evolves as the person matures. Personal experiences shape the coping mechanisms that the individual uses to deal with stressors. As psychologists explain, the coping mechanisms that were effective in the past are repeated as a first response to the pain of a loss. When older coping strategies are unsuccessful, new coping mechanisms are attempted (see Chapter 29). When faced with a loss, a patient learns what is needed for his or her own coping through repetition that is based on the successes and failures of different coping mechanisms. Sometimes the number or depths of losses become overwhelming, and familiar coping styles are not successful. For example, in the case of disenfranchised grief, society has different expectations than the person who experiences the loss, and routine coping strategies become ineffective, unavailable, or maladaptive. Professional assistance is often required to help the patient and family understand and deal realistically with losses.

Socioeconomic Status. Socioeconomic status influences a person's ability to obtain options and use support mechanisms when coping with loss. In general, people feel greater burden from a loss when financial, educational, or occupational resources are lacking. For example, a patient with limited finances may not be able to replace a home lost in a fire or may not be able to purchase necessary medications to manage a newly diagnosed disease. These patients require referral to community social service and support agencies that can provide needed resources.

Personal Relationships. When loss involves a loved one, the quality and meaning of the relationship are critical in understanding a survivor's grief experience. It has been said that to lose parents is to lose the past, to lose a spouse is to lose the present, and to lose a child is to lose the future. When a relationship between two individuals has been very close, the one left behind can have great difficulty coping. Support from family and friends is based, in part, on the person's relationships with members of a social network and the manner and circumstances of the loss. People who do not receive support and compassion from others may have difficulty grieving.

Nature of the Loss. The ability to manage grief depends on the meaning of the loss and the situation surrounding the loss. A bereaved person's ability to accept help from others influences whether he or she will be able to cope. The visibility of a loss influences the support a person receives. For example, the loss of one's home from a fire prompts support from the community, whereas a private loss of an important possession may prompt less support from others. Some losses are not highly visible, such as reproductive loss (e.g., miscarriage, stillbirth, abortion, giving up a child for adoption, infertility).

The suddenness of a loss can delay resolution from grief. For example, a sudden and unexpected death is generally more difficult for a family to accept than death after a long-term chronic illness.

* BOX 28-1 FOCUS ON OLDER ADULTS

- Bereavement adjustments are multidimensional in that nearly every aspect of a person's life can be affected by a loss. Examples are decreased social support from friends and family, and potential changes in housing.
- The overall effect of bereavement on the physical and mental health of many older spouses is not as devastating as expected. Some losses at this stage are seen as more appropriate than for younger adults.
- Older bereaved spouses commonly experience both positive and negative feelings simultaneously; however, they are at increased risk for depression.
- Loneliness and problems associated with completing the tasks of daily living are two of the most common and difficult adjustments for older bereaved spouses. Older persons are more likely to have already lost siblings or other family members, which may affect available social support and social support networks.
- Older bereaved adults adjust to the deaths of spouses in diverse ways.

Data from Worden, J. W. (2009). *Grief counseling and grief therapy: A handbook for the mental health practitioner* (4th edition). New York: Springer.

Culture and Ethnicity. A person's cultural background strongly influences attitudes toward life-sustaining treatments during terminal illness (Verosky, 2006). Cultural background and family practices also influence people's interpretation of a loss and expression of grief (Box 28-2). Culture affects how patients and their support systems or families respond to loss (see Chapter 9). For example, in the Western hemisphere, the

* BOX 28-2 CULTURAL ASPECTS OF CARE

At the end of life, rituals, mourning practices, and specific expressions of grief are necessary for participants of all cultures, in order to have a sense of acceptance and inner peace. Whether appropriate care at the end of life achieves a "good death" or an "acceptable death" for patients is controversial.

Do patients achieve a sense of comfort and peace during the death experience? Most hospital policies and procedures support an "acceptable death"—nontheatrical, disciplined, and with minimal exchange of emotions—for the patient who is dying. This means providing basic standard levels of care and support, which may or may not take into account a patient's cultural beliefs and practices. A "good death" or "acceptable death" is also known as a "meaningful death" and can be defined as a dying process "during which the patient is physically, psychologically, spiritually and emotionally supported by his or her family, friends, and caregivers" (Chochinov, 2006, p. 85). In contrast, Gillick (2009) describes a desirable death in some family or cultural situations as one that allows social adjustments and personal preparations for the transition that will occur. A good death will be perceived by families as withholding painful truths from the family member. By withholding specific illness or treatment information, the family may feel they are trying to protect their relative from suffering (Gillick, 2009). In these situations, the value of autonomy may be in conflict with culture and tradition. The disengagement that occurs between the person who is dying and loved ones takes many forms because of cultural differences:

- Some Asian Americans, Latinos, and Orthodox Jews believe that telling a person they have a terminal diagnosis will precipitate death.
- Asking patients if they would like more information on their condition or if they prefer you or the physician to speak to the substitute decision maker may be a compromise between cultural values and patient autonomy.
- Families who try to conceal painful truths or otherwise seem at odds with core nursing values such as autonomy see themselves as trying to protect their family member from suffering.
- All cultures will hold individual and varying preferences regarding treatment, involvement of family, sharing of information, and care of the dying and deceased.

Implications for Practice

- Your nursing concept of social support must be broadened to include greater variation in the timing, form, and mode of support provided to grieving patients and families.
- Cultural beliefs influence who makes up a patient's support network and what support is acceptable to both give and receive during death.
- It is not important for you as a nurse to be an expert in all cultures, but it is a necessity to identify what is culturally important or significant for the individuals and families you work with.

Data from Gillick, M. (2009). Decision making near life's end: A prescription for change. *Journal of Palliative Medicine*, 12(2), 121–125.

grieving process is usually personal and private; individuals show restrained emotion. However, the ceremonies surrounding a person's death offer time for grief resolution and reminiscing. In Eastern hemisphere nations, such as the Philippines or China, respect for the dead is shown by wailing and physically demonstrating grief for a specified period. Despite these trends, members of the same ethnocultural background may respond to loss and death differently. You must acquire an understanding and appreciation of each patient's cultural values as they apply to the experience of loss, death, and grieving.

Canada is a multicultural society, and as a nurse, you can anticipate many cultural contexts and responses to loss, death, and bereavement. You must be able to support and guide patients and families through the end-of-life process in a culturally informed and acceptable manner. Culturally sensitive practices are needed to guide the development of effective nursing interventions. When individuals lose control over aspects of their life because of illness, you must provide respectful and appropriate culturally safe care to individual patients. This is best achieved through asking specific questions of the patient or the family (Verosky, 2006).

Spiritual Beliefs. Individuals' spirituality significantly influences their ability to cope with loss. Some of the spiritual resources on which patients may depend during a loss include faith in a higher power or influence, their community of fellowship with friends, their sources of hope and meaning in life, and their use of religious rituals and practices. Loss can sometimes cause internal conflicts about spiritual values and the meaning of life. Patients who have a strong interconnectedness with a higher power or others are often very resilient and able to face death with relatively minimal discomfort (see Chapter 27). Alternatively, patients faced with a life-threatening or terminal illness may begin to question their faith and wonder why this would be allowed to happen to them.

Coping With Grief and Loss

In order to support patients and families during loss, you must understand how people normally cope with grief and loss. Nursing interventions involve reinforcing the patient's successful coping mechanisms and introducing new coping approaches. Chapter 29 summarizes the nursing care principles for assisting patients in coping with stressful situations.

Hope. Hope is the anticipation of a continued good or of an improvement in, or lessening of, something unpleasant. It is a multidimensional concept that is energizing and provides comfort while a person endures life threats and personal challenges (Smith & Kautz, 2007). Hope enhances coping skills by building on a patient's control. A person often reveals hope through an expression of expectations for life, the present, and the future. Many patients with terminal illness focus hope on milestones or something other than a prognosis (Chochinov, 2006). Spiritual distress is often based on the person's definition of hope or lack of hope. People may view hope as encouragement to work toward recovery. Other people may view hope more negatively by not being able to envision any future favourable outcomes.

Hope has purpose and direction and, in a palliative patient, can contribute to enhancing control, maintaining dignity, and sustaining relationships (Smith & Kautz, 2007). The existence and maintenance of hope depend on a person's having strong relationships and a sense of emotional connectedness to others. Nurses and other health care providers may offer that personal

connectedness essential to hope. Hope is often the basis from which patients find meaning in their illness. Hopefulness enables people to see life as enduring or having sustained meaning or purpose (Chochinov, 2006). Nurses have reported that they believe they make the greatest difference in patients' lives by helping them keep hope alive; by increasing a patient's awareness of what is possible, nurses can, in addition, maintain a renewed sense of purpose through hope (Smith & Kautz, 2007). Chapter 27 discusses the conceptual components of hope and related nursing care implications.

Critical Thinking

When you care for patients who have experienced losses, successful critical thinking requires a synthesis of knowledge, previous experience with loss and grief, and information gathered from patients and families. To provide appropriate and responsive nursing care, you must apply both critical thinking qualities and intellectual and professional standards.

During assessment, you must analyze all sources of information in order to select appropriate nursing diagnoses (Figure 28-1). To understand the process of grief and its effect on the patient and family, you integrate knowledge from nursing and other disciplines and from previous experiences in caring for

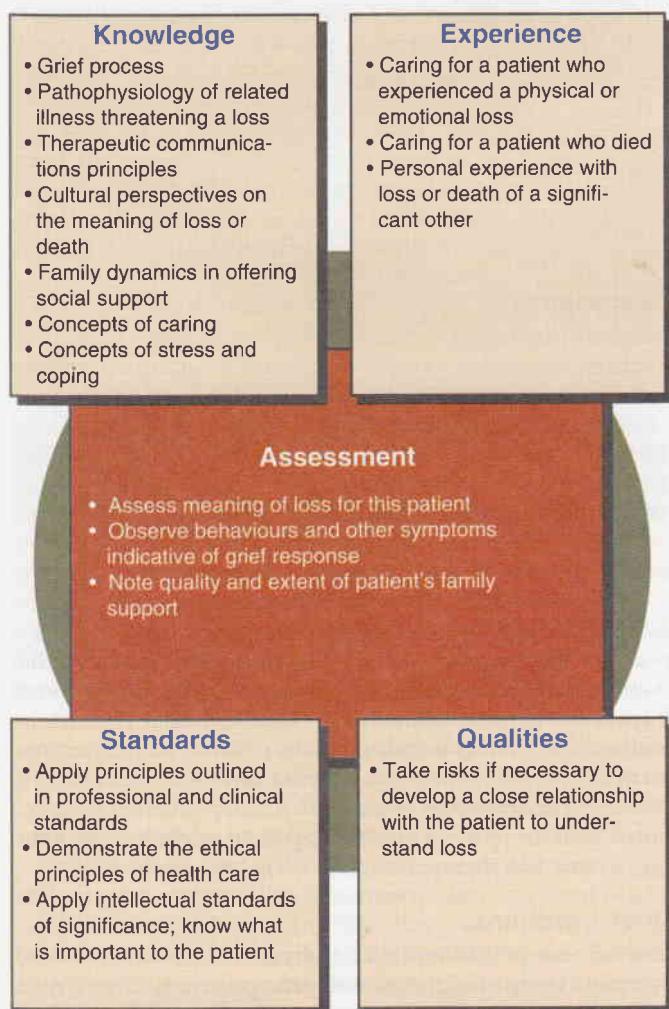

Figure 28-1 Critical thinking model for loss, death, and grieving assessment.

patients suffering loss. Knowledge of the stages of grief, for example, enables you to better empathize with a patient and family and to understand the patient's behaviours. Through identification of the stages of grief, you are able to direct assessment questions. Critical thinking qualities and standards then help you apply this information in a relevant and therapeutic way for the patient's benefit. For example, you need the critical thinking quality of perseverance so that you can learn as much as possible about the type of grief a patient is experiencing, in order to ultimately select the most appropriate nursing interventions. The use of intellectual standards such as significance and relevance helps ensure that the information gathered is pertinent to the patient's unique situation. Guiding standards include those of bioethics, the dying person's bill of rights (Box 28-3), clinical standards such as guidelines for managing cancer pain, the Canadian Nurses Association (CNA; 2008) *Code of Ethics for Registered Nurses*, and provincial regulatory bodies' professional standards and practice standards. All provide evidence-informed guidelines for a thorough assessment and humane, compassionate nursing care.

The Nursing Process and Grief

♦ Assessment

When you care for a patient who has experienced or is facing a loss, assessment includes the patient, family, significant others, and the context. Grief assessment is ongoing throughout the course of an illness for the patient and family and for the bereavement period after the death for the survivors (Verosky, 2006). You should not assume how or whether the patient or family experiences grief. You should also avoid

► BOX 28-3 A Dying Person's Bill of Rights

- I have the right to be in control.
- I have the right to be treated as a living human being until I die.
- I have the right to have a sense of purpose.
- I have the right to be cared for by those who can maintain a sense of hopefulness.
- I have the right to express my feelings and emotions about my approaching death in my own way.
- I have the right to have a respected spirituality.
- I have the right to participate in decisions about my care.
- I have the right to expect continuing medical and nursing attention even though "cure" goals must be changed to "comfort" goals.
- I have the right not to die alone.
- I have the right to be comfortable.
- I have the right to have my questions answered honestly.
- I have the right not to be deceived.
- I have the right to have help from and for my family in accepting my death.
- I have the right to die in peace and dignity.
- I have the right to laugh and to be angry and sad.
- I have the right to retain my individuality and not be judged for my decisions that may be contrary to beliefs of others.
- I have the right to be cared for by caring, sensitive, knowledgeable people who will try to understand my needs and will be able to gain some satisfaction in helping me face my death.

Figure 28-2 Nurses find a private place to listen to patients express their grief.

assuming that a particular behaviour indicates grief; rather, you should allow patients to share what is happening in their own way. An effective nurse encourages patients to tell their stories. This requires you to establish trust with patients and to evoke a caring presence. It is helpful to have patients and families find a time and place to express their grief and describe their experiences (Figure 28-2). During an assessment, you interview patients and families separately unless a patient requests having family members present. A thorough and comprehensive approach to the assessment of grief will result in a well-designed plan of care that will facilitate patients' and families' abilities to work through grief.

You begin by interviewing the patient and then the family, using honest and open communication. Listening carefully and observing the patient's responses and behaviours are important. You assume a neutral perspective and remain alert for nonverbal cues such as affect, facial expressions, voice tones, and topics that are avoided. While gathering data, you summarize and validate any impressions formed with the patient and family so that appropriate nursing diagnoses can be made. Information from other health care workers, such as physicians, social workers, and providers of pastoral care will contribute to the database.

Type and Stage of Grief

It is important to assess how a patient *is reacting* rather than how the patient *should be reacting*. The sequencing of stages or behaviours of grief may occur in order, they may be skipped, or they may recur. A single behaviour can be representative of any number of types of grief. Therefore, the identification of the type and stage of grief should be used only to guide your assessment and not to judge the outcomes of the grieving process. By understanding a theorist's phase of grief, you can accurately assess a situation. For example, if a patient is complaining of loneliness and difficulty falling asleep, you consider all factors surrounding the loss. When did the loss occur? What type of loss occurred? The patient may be experiencing a normal grief reaction, or, if the loss occurred two years ago, the patient may be experiencing chronic grief.

Ask patients to describe their loss and how it has affected them: "Tell me how your diagnosis of heart disease makes you

► BOX 28-4 Symptoms of Normal Grief

Feelings

- Sadness
- Anger
- Guilt or self-reproach
- Anxiety
- Loneliness
- Fatigue
- Helplessness
- Shock or numbness (lack of feeling)
- Yearning
- Feeling of emancipation or relief

Cognitions (Thought Patterns)

- Disbelief
- Confusion
- Preoccupation about the deceased
- Sense of the presence of the deceased
- Auditory hallucinations
- Perceptual disturbances
- Hopelessness ("I'll never be okay again")

Physical Sensations

- Hollowness in the stomach
- Tightness in the chest
- Tightness in the throat
- Oversensitivity to noise
- Depersonalization ("Nothing seems real")
- Shortness of breath
- Muscle weakness
- Lack of energy
- Dry mouth
- Headache
- Abdominal pain

Behaviours

- Sleep pattern changes
- Appetite disturbances
- Absent-minded behaviour
- Dreams about the deceased
- Sighing
- Emotional lability
- Carrying objects that belonged to the deceased

feel." You can anticipate characteristics or responses during a phase of grieving, but you should allow patients to describe their feelings as thoroughly as possible: "How has this change in your life affected you today?" "Tell me more." Then probe and validate feelings expressed in the patient's emotions: "You seem angry; tell me more" "You seem sad; tell me" "What are your feelings about ... ?" Avoid premature assumptions about the phase of grief that a patient might be experiencing, so that you do not terminate the assessment too early.

Grief Reactions

You will use psychological and physical assessment skills to compile a complete database about the patient, family, or both. Although no two people grieve exactly the same way, most people who grieve have at least some outward signs and symptoms (Box 28-4). Clinical reasoning is needed to analyze the data and cues you have collected and to determine the

appropriate related cause. For example, a patient who is experiencing dysfunctional grieving may have a changing affect, lowered activity level, somatic complaints such as headache or upset stomach, and alterations in sleep patterns, memory, and concentration. You might associate these symptoms with any number of problems such as anxiety, gastrointestinal disturbances, or even impaired memory. However, the focus is to assess the patient's symptoms in context. What are the meaning and significance of the loss, and how are they affecting the patient in physical and psychological ways? With what does the patient associate the symptoms? In what way are the symptoms related to one another when they occur? What symptoms are observed when the patient openly expresses grief? Over what time period have the symptoms been present: before the loss or during the loss? Careful analysis refines your ability to make judgements about the patient's condition.

A loss takes place in a social context. When the primary provider in a family has a terminal illness, the family begins to reorganize itself as soon as the patient is no longer able to fulfill the same number and types of roles. When a person is disabled, the patient and family undergo similar reorganization, realigning roles and responsibilities to meet demands. During this time, patients and families can experience a variety of physical and psychological symptoms. You assess the entire family's response to loss, recognizing that family members may be dealing with aspects of grief different from those of the patient. Good interviewing and physical assessment skills guide you as caregiver and as an advocate of the patient in planning appropriate nursing care. It is important to assess for any changes in family relationships or interactions during a patient's illness. Terminal illness may bring distant family members together, which can result in additional stressors on families. An awareness of this potential allows you to identify strategies for adaptive family coping if they are required.

Factors That Affect Grief

Because a number of factors influence loss and the grief response, it helps to discuss the meaning of loss to the patient and family. This discussion usually elicits information that allows you to explore a number of topics in detail, such as personal characteristics of the person experiencing loss, the nature of family relationships, support systems, and cultural and spiritual beliefs (Table 28-3). You must then apply assessment skills from appropriate specialty areas (e.g., family or spiritual assessment; see Chapters 19 and 27, respectively) to acquire a thorough understanding of the patient's loss.

End-of-Life Decisions

Serious illness or loss can add a stressful and difficult element to decision making. Time to make decisions or consider all options may be limited, or the patient may be unable to fully participate in the decision-making process (Payne, 2009). In order to preserve patient autonomy, many people are using advance directives. Advance directives may include living wills or the designation of a health care proxy. Although living wills or other advance directives may not be recognized legally in all provinces, the CNA (1994), along with other national health organizations, developed the *Joint Statement on Advance Directives*. In this document, the CNA stated that "all persons have the right to make decisions regarding their health care and treatment, including the right to request or refuse life-sustaining treatment" (p. 1). An advance directive documents a person's preferences regarding life-sustaining treatment and

communicates these preferences if the person becomes incapable of doing so for himself or herself (CNA, 1998). This upholds the nursing professional value of autonomy. There are some disadvantages to advance directives. A living will limits treatment; however, instructions in a living will may not adequately cover the uniqueness of each potential situation (Payne, 2009). A **health care proxy** is designated in advance by the patient, knows the patient's wishes regarding treatment and life-sustaining procedures, and ideally would live locally (Sabatino, 2010). As a nurse, you must be aware of the legal status of advance directives in your province or territory and the laws regarding a person's competence to consent to treatment, as well as legislation regarding the selection and responsibilities of substitute decision makers or a health care proxy (see Chapter 8).

When a person has a terminal illness, family members must face end-of-life decisions that have ethical, legal, and practical implications. Families may experience higher levels of stress, discomfort, or even guilt when deciding whether to initiate or withdraw life-sustaining treatments. Some treatments may offer symptom relief but simultaneously prolong life, which creates conflict or dilemmas for families and caregivers. Although some patients may have advance directives, it is important for family members to know in advance a patient's wishes in regard to life-sustaining measures. At times, family members may disagree with each other about treatment plans, or the values of the family may be in conflict with those of the health care provider. Situations such as these often result in ethical dilemmas for families, nurses, or other care providers. Decision making related to ethical situations should consider the primary nursing values from the CNA (2008) *Code of Ethics for Registered Nurses*. Ethicists and ethical decision-making models may be used if agreement on treatment is not possible.

The *Code of Ethics for Registered Nurses* (CNA, 2008) identifies three values that are pertinent to nurses assisting individuals in end-of-life decision making:

1. Promoting health and well-being: Nurses must ensure that an individual's wishes as stated in an advance directive are respected and that continuing care and support are provided.
2. Promoting and respecting informed decision making: Nurses must respect and promote the autonomy of individuals, help patients express their needs and values, and help patients obtain appropriate care.
3. Preserving dignity: Nurses must advocate on the patient's behalf and examine biological, psychological, social, cultural, and spiritual factors that affect end-of-life treatment decisions.

Responsibility statements associated with each value in the code give more direction to nurses in upholding the values. For example, the value "health and well-being" includes this responsibility statement: "When a person receiving care is terminally ill or dying, nurses foster comfort, alleviate suffering, advocate for adequate relief of discomfort and pain and support a dignified and peaceful death" (CNA, 2008, p. 14).

The National Consensus Project (NCP, 2009) has articulated a set of major domains and clinical practice guidelines regarding end-of-life care. You must assess the patient's and family's wishes for end-of-life care, including the preferred place for death, the use and extent of life-sustaining measures, cultural-specific expectations, and expectations regarding pain control and symptom management (Box 28-5). Does the patient want to try all available treatments? Does the family or patient insist

► **TABLE 28-3** Assessment of Factors That Influence Grieving

Factor	Areas, Suggestions, and Questions to Explore
Nature of relationships	Functions of the family, community, and society <i>Examples:</i> "How long have you known your friend?" "What role has your mother played in your family?" "What is your relationship? Will it change?" "How will family relationships change as a result of the loss?"
Social support system	Availability of family, friends, health care providers <i>Examples:</i> Who is present? Absent? Supportive? Nonsupportive? What do family and friends do that is most meaningful? Are family and friends available when needed? Are health care providers accepting and exploring ways to preserve the patient's dignity and lifestyle?
Nature of loss	Actual versus perceived; death issues; impact on roles <i>Examples:</i> "Tell me what the loss means to you." "What factors help you to grieve?" "What factors interfere with grieving?" "What past experiences or outcomes have you had with loss?"
Cultural and spiritual beliefs	Values, cultural norms, spirituality, customs, attitudes <i>Examples:</i> "What is your belief about death? About the meaning of life?" "What customs do you value at the time of death?" "How is this loss viewed by other people of your culture or religious group?" "Do medical treatments interfere with religious practices?" "Who has the right to say yes or no to life-sustaining measures?"
Loss of personal life goals	Actual or perceived individual losses affecting future decisions and options <i>Examples:</i> "What is your goal in life for ... ?" "How has this goal changed as a result of your diagnosis?" "How will your role change your personal goals?" "What planning have you and your family made for your own life?"
Family's grief	Relationships, involvement with the dying process <i>Examples:</i> Observe patient and family's level of grief, patterns of behaviour, rank of leadership or power. What has helped family members deal with problems in the past? What was not helpful? What are the family's strengths and weaknesses?
Survivor risk factors	High risk, such as sudden death, violent death, loss of a child <i>Examples:</i> "Describe your feelings at this time." "Let's talk about why you think you could have prevented this. Are you feeling guilty because ... ?" "What are unresolved issues or perceptions toward others?"
Hope	Goals, worth, adaptation to future changes <i>Examples:</i> "Tell me what you think about your treatment plan." "What do you expect will happen to you?" "How does this illness affect your goals in life?" "What are you hoping for after your surgery?"

on the use of a feeding tube for continued nutritional support after the patient stops eating? When life support requires use of a mechanical ventilator, is this something the patient wants? Does the family feel comfortable in administering analgesics? You must give the patient and family time to discuss their preferences. Often it is necessary to return to a conversation on a subsequent day or visit. If you feel uncomfortable in assessing a patient's wishes, it is important to find a health care provider who is experienced with discussing end-of-life issues and can assist in communicating a patient's preferences to the

health care team. For example, physicians may be helpful when discussing issues related to probability or futility, or a social worker may be able to help with decision making with regard to family roles, responsibilities, and relationships.

End-of-life care is one of the more significant topics you will discuss with patients (Box 28-6). Good interdisciplinary teamwork is essential to provide quality end-of-life care. Thus, you must communicate what is known about patient preferences and decisions in change-of-shift reports, health team conferences, written care plans, documentation in the patient's

* BOX 28-5 RESEARCH HIGHLIGHT

Family Perception of End-of-Life Care

Research Focus

Family members are often involved in providing care during a dying person's last month of life, regardless of the setting (home, hospice, or hospital). Their perspectives of how the person's last days of life are spent provide valuable insight into the quality of end-of-life care.

Research Abstract

Radwany et al. (2009) conducted a retrospective study of bereaved family members. The research obtained information from 23 family members following the death of a loved one from a terminal illness. Data about the emotional burden and experiences of families regarding end-of-life decision making, the illness experience, and the dying process were collected. Findings suggested that residual emotional burden may linger. Aggressive life-sustaining treatments were not used extensively, and decisions to forgo or discontinue aggressive treatments were very difficult for families. Families prefer to fully understand the condition of the patient with a very clear awareness of the severity and course of the illness. Families stated they felt they needed more information in advance to prepare them for the dying process, so they would know what to expect.

Evidence-Informed Practice

- It is important to learn directly from patients and families their understanding of the illness.
- Families of dying patients may have great difficulty making decisions about the cessation of some curative treatments.
- You should recognize that family members carry a significant emotional burden, particularly with respect to decision making, and will need your support.
- You should provide guidance and support to help families understand the dying process. Families need to know in advance what they may expect to see throughout the dying process.

record, and ongoing consultation with physicians and other health team members.

Nurses' Experience With Grief

When caring for grieving patients, you must assess your own emotional well-being. Self-reflection, which is a part of critical thinking, is a valuable tool in assessing whether a person's sadness is related to the patient, to unresolved personal experiences from the past, or to a combination of both. It is normal to have personal feelings and emotions about certain illnesses and death. However, it is inappropriate to emphasize your personal family situations and values over those of the patient. Talking with friends and professional colleagues may help you to resolve conflicts about caring for dying patients. Some nurses choose to work in a specialty area in which deaths are usual. Close bonds between nurses and patients often develop in these situations. Part of being a professional involves knowing yourself and when to move away from a situation. Nurses who choose to work in palliative care settings obtain support from their peers, as well as from interdisciplinary team debriefings. Nurses may not always identify maladaptive

BOX 28-6 NURSING STORY

Nursing Roles With Loss, Grief, and End-of-Life Issues: John's Story

Nurses from many areas and disciplines are involved in the experiences of loss, death, and grief. John is an 81-year-old with recurrent small-cell lung cancer and is considered eligible for palliative care. Several years ago, he received a diagnosis of limited-stage small-cell lung cancer. A course of chemotherapy and radiotherapy resulted in a remission of several years' duration. Subsequent follow-up revealed that the cancer had returned, and John's condition was considered terminal. Throughout John's experience with his illness, he has interacted with many nurses with varying roles and responsibilities. Although these nurses all had different roles, functions, and work areas, they were all involved and sharing with John and his family's sense of loss, grief, celebrations, and eventual preparation for death.

Initially, John interacted with the clinic nurse at his family physician's office. Although not involved directly in his care, this nurse was able to provide support, reassurance, and encouragement each time John visited the office. While John was receiving his treatments at the cancer centre, he relied on the chemotherapy clinic nurses to check how he was feeling, and he counted on them to be caring but not gloomy, to keep his spirits up, and to encourage him to keep "fighting" while it was beneficial. One nurse in particular had frequent contact with John, and he looked forward to seeing her. She was a clinical trials research nurse, and John had enrolled in a medication trial. This advanced practice nurse was, to John, like his own private nurse, someone who wanted to see him regularly, took a genuine interest in him, and provided tremendous support to him and his family.

Home care nurses also played an important role in John's experience. The initial home assessment, enrolment in a community palliative care program, and discussion of "do not resuscitate" protocols were managed in a caring and compassionate manner. John's health is now relatively stable and appears to have reached a plateau in the disease course. Each time the home care nurse visits and performs her assessment and documentation, John sees this as a "social" visit but finds the support to be very important. Being a reserved person, John finds it easier to discuss some of his issues with a professional. John has not decided yet whether he wishes to die at home or in a hospital; however, caring and compassionate palliative care nurses will at that point become key components of John's and his family's experience.

John's story is not unique, and most nurses are involved in the experience of loss, death, and grief, regardless of the area of practice. Having a sound understanding of these concepts will enable you to provide supportive, understanding, and compassionate care to your patients, anywhere along the continuum of life, loss, grief, and eventually death.

coping behaviours themselves, and the entire team has a responsibility to recognize and support ineffective coping in their colleagues (Rollings, 2008).

Patient Expectations

You must assess the patient's and family's expectations for nursing care. Patient perceptions and expectations can influence how you prioritize nursing diagnoses. For example, if patients perceive their pain and discomfort as severe, they will be less attentive to attempts to discuss the significance and meaning of their loss. Before you can begin meaningful

discussion or counselling, the patient must be comfortable. On occasion, patients are hesitant to accept, and families reluctant to administer, narcotic analgesics because of fears of addiction.

Significant medication teaching may be required in these situations. Once the patient is assessed as comfortable and the patient considers the pain level acceptable or under control, you should assess the patient's expectations within the context of the loss by asking questions such as "How can we help you cope with your loss?" "What do you feel is necessary from us for you to be able to manage the grief you feel?" "What is most important that we do for you while you are under our care?"

It is important to give family members the chance to explain how they perceive your role, explain what they think are the goals of the health care team, and ask any questions they may have. This helps you clarify any misunderstandings that might exist. For example, the family may have unrealistic expectations regarding the treatment available to the patient and the anticipated effects, or different family members may have conflicting opinions.

❖ Nursing Diagnosis

From data collected during assessment, you identify a nursing diagnosis that accurately reflects the needs of the patient or family experiencing the loss. Critical thinking skills are the tools used to apply concepts of assessment, clustering of cues, and drawing a conclusion of the actual or perceived needs of the patient. You cluster defining characteristics and identify the nursing diagnosis applicable to the patient's situation (Box 28-7). Clustering of patient or family behaviours, actual or potential losses, the patient's attempts at coping, and data involving the nature and meaning of the loss will lead to individualized nursing diagnoses, such as the following:

- *Anticipatory grieving*
- *Anxiety*
- *Caregiver role strain*
- *Compromised family coping*
- *Dysfunctional grieving*
- *Fear*
- *Hopelessness*
- *Ineffective coping*
- *Ineffective denial*
- *Powerlessness*
- *Readiness for enhanced spiritual well-being*
- *Social isolation*
- *Spiritual distress*

The presence of one or two defining characteristics is usually insufficient for an accurate diagnosis. You must carefully review the data to consider whether competing diagnoses exist. For example, if a dying person cries, displays anger, and reports nightmares, this could signal several possible nursing diagnoses, as these characteristics are common to more than one diagnosis. Possibilities include *pain*, *ineffective coping*, and *spiritual distress*. You examine all available data and inquire about and observe for the presence of other behaviours and symptoms until you can identify an accurate diagnosis.

Part of the diagnostic process is to identify the appropriate related factor for each diagnosis. For example, *dysfunctional grieving related to the loss of the ability to walk from paralysis* necessitates different interventions than does *dysfunctional grieving related to the loss of a job*.

In order to promote a holistic approach to care, wellness-oriented diagnoses need to be included, such as *readiness for*

► BOX 28-7 NURSING DIAGNOSTIC PROCESS

Assessment Activities	Defining Characteristics	Nursing Diagnosis
Ask patient to discuss future goals and plans.	Patient sighs and says, "I have no future."	<i>Hopelessness related to failing physical condition</i>
Observe patient's nonverbal behaviour.	Patient becomes passive with little affect and turns away from speaker.	<i>Ineffective individual coping related to low mood, and inability to manage loss</i>
Offer patient choices and observe responses.	Patient shrugs and says, "What does it matter?"	<i>Powerlessness related to perceived poor outcomes</i>
Assess activity level.	Patient refuses to eat. Patient sleeps all the time, keeping blinds closed and lights out. Patient refuses to participate in care.	<i>Self-care deficit related to inability to perform activities of daily living</i> <i>Social isolation related to inability to cope with loss</i>

enhanced spiritual well-being. These diagnoses allow for recognizing and drawing from patient strengths. In addition, the nursing diagnostic process is continual because the patient situation will change.

When identifying nursing diagnoses for the dying patient, other problems are identified separately according to specific standards of care. Other nursing diagnoses can include *disturbed body image*, *impaired physical mobility*, or *ineffective role performance*. More physical nursing diagnoses are identified when the patient begins to experience physical changes accompanying the progression of illness, including *impaired urinary elimination and/or bowel incontinence*, *acute pain*, *nausea*, *disturbed sensory perception*, and *ineffective breathing pattern*. The comfort of dying patients, including specialized pain control and acceptance of the dying process by the family, is a realistic expectation. With terminal illness, physical assessment of the dying process is ongoing so that you can adapt or validate the actual nursing diagnoses with the patient's changing condition.

❖ Planning

Grieving is the natural response to loss and thus has a therapeutic value. The focus in planning nursing care is to support the patient physically, emotionally, developmentally, and spiritually in the expression of grief. Figure 28-3 illustrates the interrelatedness of critical thinking factors during the planning phase of the nursing process. Through critical thinking, you ensure a well-designed plan in which you support the patient's personhood, self-esteem, and autonomy by including the patient in making decisions about the plan of care. When caring for the dying patient, it is important to devise a plan that helps a patient die with dignity and offers family members the assurance that their loved one is cared for compassionately

Figure 28-3 Critical thinking model for loss, death, and grief planning.

(Box 28-8). The care planning process is highly individual to the patient and family, and when possible, both must be included as active participants in your planning, goal setting, and development of realistic interventions and timelines.

Goals and Outcomes

You establish realistic goals and expected outcomes on the basis of a patient's nursing diagnoses. Patient resources such as physical energy and activity tolerance, supportive family members, spiritual faith, and methods for coping are integrated into the plan of care. For example, if a patient with a life-threatening illness has the diagnosis *powerlessness related to planned cancer therapy*, a goal of "Patient will be able to discuss expected course of disease" is realistic if the patient is able to remain attentive and participate in educational discussions without becoming fatigued. In contrast, the expected outcome "Patient will participate in series of short planned teaching discussions about disease" accounts for the patient's need for teaching sessions to be short to avoid exhaustion.

Goals of care for a patient dealing with loss might be long or short term, depending on the nature of the loss, the patient's phase of grieving, and the nature of the illness. Many terminally ill patients experience plateaus (periods of relatively stable health) interspersed with periods of exacerbation of symptoms. Because a patient may move back and forth between phases of grief, you may need to revise goals and outcomes to ensure that they remain relevant. Help from the patient's partner in deciding which goals are relevant is important. General nursing care goals for patients with a loss include accommodating grief, accepting the reality of a loss, and renewing regular relationships. When a patient has a terminal illness, controlling pain and symptoms, maintaining autonomy, and achieving spiritual comfort are important goals. For the goal "achieving a sense of dignity," expected outcomes might include the following:

BOX 28-8 NURSING CARE PLAN

Ineffective Coping

Assessment

Jan Runyon is the nurse who admits Mr. Miller, a 48-year-old man, from the emergency department to the intensive care unit (ICU) after traumatic brain injury incurred in a motor vehicle accident. Mr. Miller is a successful business executive who has a wife and two sons. The physician has explained to the family that Mr. Miller's prognosis is poor. Tests are underway to determine the extent of brain injury. Mrs. Miller and the children are in the ICU waiting area, waiting on word about Mr. Miller.

Assessment Activities

Jan asks Mrs. Miller, "Tell me how you are feeling about your discussion with the physician."

Jan observes Mrs. Miller's interaction with her children.

Jan overhears Mrs. Miller on the phone in the waiting area.

Jan accompanies the transplant coordinator, who asks Mrs. Miller if the family has ever discussed organ donation.

Findings and Defining Characteristics

"I know they are doing everything they can. He is going to be okay, I just know he is. He has never been sick a day in his life."

Mrs. Miller has difficulty problem solving. The family has posed several questions to her as to what she plans to say to Mr. Miller's employees. Mrs. Miller is unable to decide what to say at this time.

Mrs. Miller states over the phone, "Don't worry, he's having some tests right now. I know Bill: he'll be back in the office before you know it. Tell the staff everything will be okay."

Mrs. Miller responds, "Bill will be fine. That's not important right now!"

Nursing Diagnosis: Ineffective coping related to husband's traumatic brain injury and poor prognosis

Continued

► BOX 28-8 NURSING CARE PLAN—cont'd

Planning**Goal (Nursing Outcomes Classification)***

Wife will accept the fact that the patient will probably die within 48 hours.

Wife will demonstrate effective expression of grief within next 48 hours.

Expected Outcomes**Grief Resolution**

Wife will verbalize to caregiver within the next 6 hours that husband's death is actually imminent.

Wife will inform children within 24 hours of their father's likely death.

Wife will make a decision about organ donation within the next 12 hours.

Wife will discuss immediate lifestyle changes that will occur as a result of husband's death over next 48 hours.

Wife will discuss with children their concerns about what they need to do as a family to prepare for father's impending death within next 48 hours.

Wife will discuss effects loss has on her personally with caregiver within next 48 hours.

*Outcomes classification label from Moorhead, S., Johnson, M., & Maas, M. L. (2008). *Nursing outcomes classification (NOC)* (4th ed.). St Louis, MO: Mosby.

Interventions (Nursing Interventions Classification)[†]**Presence**

Display interest in wife's situation and accept her behaviours of denial.

Establish trust and a positive regard by creating an atmosphere of sharing. Offer privacy and security.

Grief Work Facilitation

Offer wife encouragement to explore and verbalize feelings of grief.

Identify personal coping strategies used in the past; assess their effectiveness, and promote them when appropriate.

Determine wife's acceptance of available community resources and initiate as appropriate: significant other (business partner), children, clergy, or other health care providers.

Rationale

Recognizing denial (based on Kübler-Ross's [1969] theory) gives the staff direction for planning unique interventions based on grief theory (Verosky, 2006).

Privacy offers a place of security to exhibit personal needs and to work through feelings (Chochinov, 2006). Anxiety about losing dignity when expressing grief will hinder an honest expression of feelings.

Encouragement refocuses on current needs and assists in initiating grief process.

Previously successful coping strategies are the first to be used when a person is under stress (Grassi, 2007). Discouraging maladaptive behaviours helps minimize dysfunctional grieving.

Professionals can use their expertise to direct the grieving process (Verosky, 2006). Trust in relationships already formed will speed the therapeutic communication process.

[†]Intervention classification labels from Dochterman, J. M., Bulechek, G. M., & Butcher, H.K. (2008). *Nursing interventions classification (NIC)* (5th ed.). St Louis, MO: Mosby.

Evaluation**Nursing Actions**

Say to patient's wife, "This has been a difficult time. Your husband's injury has been so sudden."

Ask, "Tell me how you are feeling now."

Observe wife's behaviour when with children. Wife discusses decisions that must be made.

Patient Response and Finding

Wife responds, "I still cannot believe it. The doctors do not believe he will live through the night."

Wife explains, "I am worried about my kids. Both boys are close to their dad. I feel this unbelievable sadness."

Wife discusses decisions that must be made because of impending death of husband. She allows the children to express their sadness.

Achievement of Outcome

Wife begins to acknowledge patient's impending death.

Wife is able to express normal grieving behaviours.

Wife is able to express grief with family; maintains role as supportive mother.

- Patient will be able to continue parental responsibilities in care of toddler.
- Patient will express hopefulness that cancer treatment will control symptoms.
- Patient will engage in playing chess with friends on a weekly basis.

Setting Priorities

When a patient has multiple nursing diagnoses, the problems cannot be addressed simultaneously. At any given time, two or three problems dominate your attention. Figure 28-4 is a concept map developed for a patient with a medical diagnosis of depression after the death of his wife six months previously.

Figure 28-4 Concept map for a patient with depression after the death of his wife.

As a result of the patient's medical condition, associated health problems include the nursing diagnoses *dysfunctional grieving*, *disturbed sleep pattern*, and *imbalanced nutrition: less than body requirements*. You must determine which of the three diagnoses necessitates greater attention. The continuing grief experienced by the patient might be the focus. Until the patient is able to accept his loss and begin resolving his grief, he may be unable to attend to interventions that will improve his nutritional intake and sleep status.

Patients' conditions always change. In the ongoing assessment of a patient's condition, you can quickly discover a new problem. You must always consider which of the patient's most urgent physical or psychological needs require immediate intervention. You consider the patient's expectations and preferences in regard to the priorities of care. If a terminally ill patient's priorities include controlling pain and maintaining self-esteem, pain control is the priority when analgesics become ineffective and the patient experiences acute distress. If the patient is progressing as desired, you may refocus priorities to address unmet needs. For example, the patient suffering depression caused by his wife's death also has problems of imbalanced nutrition and disturbed sleep pattern. If the patient reports improved appetite and has shown weight stabilization since the last clinic visit, you can focus more attention on the sleep pattern disturbance. You must remember that the patient's expectations, clinical condition, and preferences influence priorities. If a terminally ill patient places more emphasis on spiritual support than on other priorities such as learning about planned treatments, you must attend to the patient's priorities. Meeting patient priorities may allow you to then address other needs more effectively with less effort.

Continuity of Care

Interdisciplinary teams help identify and meet the needs of people who experience losses. Dietitians, clergy, physicians, social workers, physiotherapists, psychologists, chaplains, and other specialty health care providers can assist a patient and

family in their grief. A coordinated team approach to managing a patient's needs results in a well-managed care plan. When a patient dies, the loss that you and your colleagues experience can be shared within the interprofessional group. Support is needed to promote healing for all who worked with the dying patient and the family. Conflicts and differences can be discussed openly and solutions found in a healthy manner with the patient as the primary focus. For example, ethical conflicts may have arisen related to proposed or performed medical treatments or interventions. Through working together, the sharing of experiences, feelings, alternatives, and solutions becomes the basis for dealing with future losses.

Many terminally ill patients return home and require continued intensive nursing care. Home care nurses collaborate closely with family members to meet the patient's ongoing needs. Important interventions to include in planning a return home are arranging for main-floor access, arranging appropriate medical equipment, and providing sufficient family respite. When it is realistic for the patient to remain independent, therapeutic strategies should bolster the patient's sense of autonomy and the ability to function as independently as possible (Smith & Kautz, 2007). For example, judicious application of orthotic devices, along with physiotherapy and occupational therapy, can often bolster a patient's functional capacity. In the home, safety issues related to the environment may exist, and patients often benefit from nurse-initiated referrals to community occupational therapists.

Implementation

Health Promotion

Although a return to full function is not an expected outcome for a terminally ill patient or even for a patient who has significant disability, optimal physical and emotional functioning is a realistic goal. The goal of nursing care is to help patients and families cope with the stressors in their lives and to achieve healthy grief resolution. You help patients and families in

dealing with loss, making decisions about the patient's health care, and adjusting to any disappointment, frustration, and anxiety created by their loss.

Therapeutic Communication. Nursing care of the grieving patient and family begins with establishing a caring presence and determining the significance of their loss. This is difficult if the patient is unwilling or unable to express feelings or is experiencing numbing or denial. You must use therapeutic communication strategies that enable patients to discuss their loss and find ways to work through it. Your presence, attentive listening, and use of open-ended questions enable patients to freely share their thoughts and concerns. Closed-ended questions often reflect only what you presume is the problem. For example, in response to the question "Does knowing you have cancer make you fearful?" a patient will probably not reveal as much as to "Tell me how your diagnosis of cancer is making you feel." You should acknowledge the patient's grief and show support by demonstrating caring behaviours throughout the discussion (see Chapter 18). You will gain the patient's trust by showing a desire to enter into a caring, therapeutic relationship with the patient. Listening attentively to the patient can be very therapeutic for the patient, and you may discover details that help you plan effective care.

If a patient chooses not to share feelings or concerns, you should convey a willingness to be available when needed. If you are reassuring and respectful of the patient's need for dignity and privacy, a therapeutic relationship will probably develop. Sometimes patients need to begin resolving their grief before they can discuss their loss.

Some patients will not discuss feelings about their loss, or sometimes a patient does not want to discuss loss, symptoms, or impending death. You must observe for expressions of anger, denial, depression, or guilt. You must also know your own feelings before encouraging patients to express their anger. Individuals may express anger toward family, staff, or physicians. Patients can also become demanding and accusing. You must remain supportive by letting patients and family members know that feelings such as anger are normal. For example, you might say, "You are obviously upset. I just want you to know I am here to talk with you if you want." You must avoid barriers to communication such as denying the patient's grief, providing false reassurance, or avoiding discussion of sensitive issues (see Chapter 17).

No topic that a dying patient wishes to discuss should be avoided. When the patient wants to talk, it is important for you to find time to do so. This can be challenging for a nurse with limited experience with dying patients or who works in a busy acute care setting. You should respond to questions openly and honestly and provide information that helps patients and their families to understand their condition, the trajectory or future course of their disease, the benefits and burdens of treatment, and values and goals (Verosky, 2006). In some cases, you may recognize the need for pastoral care or counselling services, and you can initiate a referral for the patient to consult with such professionals.

Promoting Hope. Hope can be an energizing resource for patients experiencing loss. For each dimension of hope, nursing strategies that promote hope exist.

- *Affective dimension:* Show empathic understanding of the patient's strengths. Reinforce expressions of courage, positive thinking, and realistic goal setting. Encourage expression of both positive and negative feelings.

- *Cognitive dimension:* Offer information about the illness and treatments, and correct any misunderstanding or misinformation. Clarify or modify the patient's perceptions.
- *Behavioural dimension:* Assist the patient in using personal resources and making use of external supports to balance the need for independence with healthy interdependence and dependence.
- *Affiliative dimension:* Encourage patients to foster supportive relationships with others.
- *Temporal dimension:* Focus on short-term goals as life expectancy diminishes.
- *Contextual dimension:* Encourage development of achievable goals. Allow time to reminisce about achievements or positive moments.

Facilitating Mourning. Nursing care strategies can help patients move through uncomplicated grief (Worden, 2009). The following guidelines are helpful for people who are mourning a death, facing death, or grieving over an actual loss:

- *Help the patient accept that loss is real.* Discuss how the loss or illness occurred or was discovered, when, under what circumstances, who told the patient about it, and other similar topics to help make the event real and to place it in perspective.
- *Support efforts to live without the deceased person or in the presence of disability.* A problem-solving approach is often helpful. Have patients or the family make a list of their problems, help them prioritize the problems, and then lead them step by step through a discussion of how they might tackle each one. Encourage them to rely on other family members, community resources, or other people who can help.
- *Encourage establishment of new relationships.* Many people fear that establishing new relationships would be disloyal. They need reassurance that new relationships do not mean that they are replacing the person who has died. Encourage the patient to become involved in nonthreatening social relationships (e.g., religious gatherings, volunteer activities).
- *Allow time to grieve.* It is common to have "anniversary reactions" around the time of the loss in subsequent years. Some people worry that they are mentally or emotionally unstable when sadness or other signs of grief recur after a period of relative calm. Encourage the patient to reminisce.
- *Interpret "normal" behaviour.* Being distractible, having difficulty sleeping or eating, thinking one has heard the deceased's voice, or dreaming about the deceased are common after loss. These symptoms do not mean an individual has an emotional problem or is becoming ill in some way. Reinforce the fact that these occurrences are normal and will resolve over time.
- *Provide continuing support.* Patients and their families may need to talk and may look to you for support for many months or years after a loss. If you have occasion to see the patient or family after an extended time, it is appropriate to ask about how they are coping or adjusting. This gives them the opportunity to talk if they need to.
- *Be alert for signs of ineffective coping.* Be aware of coping mechanisms that may be maladaptive, such as increased alcohol or substance abuse, which can include excessive use of over-the-counter pain medications or sleep aids.

Acute Care

Palliative Care. For people who face life-threatening illnesses, medical and technological advances are available to

reverse the course of the disease or prolong life. For patients with serious life-limiting illness, it becomes important for health care providers to find ways to help patients approach the end of life. The aim of **palliative care** is to relieve suffering and improve the quality of living and dying (Chochinov, 2006). Not all patients and families who would benefit from palliative care services will receive them. Some patients and families will “leave no stone unturned” and therefore will not accept that the patient is dying. In situations where patients become suddenly ill or symptoms do not appear until late stage terminal illness, the patient and family have not had time to grieve the loss and subsequently accept the impending death. In other cases, palliative care resources may be limited, may not be available in a timely manner, or may not be available at all.

Palliative care is for any age, any diagnosis, and at any time, not just during the last few months of life. Chochinov (2006) explained that when preservation of dignity becomes the goal of palliation, care options encompass the physical, psychological, social, spiritual, and existential aspects of the patient's illness. Palliative care thus allows patients to make more informed choices, better alleviate symptoms, and have more opportunity to manage unfinished business. Ferris et al. (2002) designed the *Model to Guide Patient and Family Care*, which provides a comprehensive approach for palliative caregiving with nationally accepted principles and norms of practice.

According to the World Health Organization (2008), when health care providers supply palliative care, they do the following:

- Provide relief from pain and other distressing symptoms
- Affirm life and regard dying as a normal process
- Neither hasten nor postpone death
- Integrate psychological and spiritual aspects of patient care
- Offer a support system to help patients live as actively as possible until death.
- Offer a support system to help families cope during the patient's illness and their own bereavement
- Enhance the quality of life

Chochinov (2006) added that palliative care also helps patients and families “combine the best of modern medicine and symptom management techniques [and] provides an opportunity to achieve dignity-conserving end of life care” (p. 84) and “encompasses the psychosocial, existential and spiritual aspects of the patient's experience” (p. 84).

Palliative care is a philosophy of total care. A palliative care approach ensures that a patient experiences a “meaningful death,” free of avoidable pain and suffering, in accordance with the patient's and family's wishes, and “is the difference between technically competent symptom management [and] a holistic approach to end of life care” (Chochinov, 2006, p. 84). Palliative care is highly dependent on an interdisciplinary team-based approach, in which each team member has individual expertise and makes an individual commitment to common goals. The team includes physicians, nurses, social workers, pastoral care providers, physiotherapists, occupational therapists, and pharmacists. Massage therapists, music therapists, or art therapists—who provide alternative therapies—might also be a part of the team (see Chapter 34). Volunteers are also part of the team and can provide additional psychosocial support and simple comfort measures.

The Canadian Hospice Palliative Care Association Nursing Standards Committee (2005) has developed nursing standards of practice for hospice palliative care. These nursing norms strive to ensure that knowledgeable and skilled caregivers are

available and are supported. Goals of the guidelines include revealing any gaps in the care of a patient and giving guidance to management of the health care resources consistent with the palliative care philosophy.

Palliative care is compassionate and supportive of dying people and their families. Nurses play a key role in providing care to the dying because of the intimate nature of the nurses' work, and the fact that they are present with the patient and families, often for 8 or 12 hours at a time, depending on the context. Thus, one of the most important skills you provide in palliative care is establishing a caring relationship with both patient and family. It also becomes very important for you to provide appropriate symptom-control measures for maintaining the patient's dignity and self-esteem, to prevent feelings of abandonment or isolation, and to provide a comfortable and peaceful environment at the time of death.

Symptom Control. Comfort for a dying patient requires management of symptoms of disease and therapies. For many patients, symptom distress is characteristic of the dying experience (Chochinov, 2006). *Symptom distress* is the experience of discomfort or anguish related to the progression of a disease. Patients experience anguish from not knowing or being unaware of aspects of their health status or treatment. Worry and fear are common among patients and may heighten their perception of discomfort. You assess the character of the patient's symptoms carefully in order to select appropriate therapies. Chapter 41 details the assessment of pain. By providing information about treatment options or the anticipated course of an illness, you help preserve the dignity of patients and families (Radwany et al., 2009). Complementary therapies are sometimes used for symptom management: for example, therapeutic touch, massage, aromatherapy, music therapy, bio-feedback, homeopathy, acupuncture, and relaxation therapy. On occasion, patients may inquire about culture-specific complementary therapies. In some jurisdictions, up to 86% of hospice programs are offering complementary therapies, with the most popular being massage, music therapy, energy healing, guided imagery, and aromatherapy (Horowitz, 2009). Chapter 34 discusses complementary therapies in more depth.

One symptom common among terminally ill patients is dyspnea (air hunger). The sense of suffocation can cause anxiety or panic in the patient and significant stress in the caregiver (Kouch, 2006). As the patient's anxiety increases when he or she is unable to breathe adequately, the dyspnea worsens. Family who are in attendance may likely become more anxious. Radwany et al. (2009) interviewed family members of terminally ill patients and found that collaborative decision making, including the patient's views, helps the patient maintain a sense of control and also decrease the emotional burden on the family related to decision making. For example, a patient may choose to switch oxygen devices, even though they deliver the same concentration of oxygen. However, if the patient believes that a different device makes a difference, the switch might be enough to relieve the dyspnea at least briefly. A patient who is breathing by mouth may receive more benefit from a mask than from a nasal cannula; however, a mask can also increase anxiety, which results in worsening dyspnea. When options in respiratory therapy exist, it helps to give the patient a choice.

Management of air hunger also involves the judicious administration of morphine and antianxiolytics for relief of respiratory distress. Table 28-4 summarizes nursing care measures for additional symptoms of terminal disease. Because

► **TABLE 28-4 Promoting Comfort in Terminally Ill Patients**

Symptoms	Characteristics or Causes	Nursing Implications
Discomfort	Any source of physical irritation may worsen pain. As patient approaches death, mouth remains open, tongue becomes dry and edematous, and lips become dry and cracked. Blinking reflexes diminish near death, which causes drying of the cornea.	Provide thorough skin care—including daily baths, lubrication of skin, and dry, clean bed linens—to reduce irritants. Assess for appropriateness of special mattresses. Provide oral care at least every 2 to 4 hours. Use foam or premoistened swabs for frequent mouth care. Apply a light film of water-soluble lubricant to lips and tongue (see Chapter 37).
Fatigue	Metabolic demands of a cancerous tumour cause weakness and fatigue. Exhaustion phase of the general adaptation syndrome causes energy depletion.	Remove crusts from eyelid margins. Administer artificial tears to reduce corneal drying. Help patient identify values or desired tasks; then help patient conserve energy for only those tasks. Promote frequent rest periods in a quiet environment. Time and pace nursing care activities (ensure periods of rest between blocks of care).
Nausea	Nausea may occur as a side effect of medications and as a result of severe pain, as a symptom of certain illnesses, or as a result of palliative chemotherapy or radiation therapy.	Encourage use of energy-saving devices such as mobility aids. Administer antiemetics: provide oral care at least every 2 to 4 hours; offer clear liquid diet and ice chips; avoid liquids that increase stomach acidity, such as coffee, milk, and citric acid juices. Encourage high-calorie nutritional supplements (e.g., Ensure, Boost).
Constipation	Narcotic medications and immobility slow peristalsis. Lack of bulk in diet or reduced fluid intake may occur with appetite changes.	Provide preventive care, which is most effective: increase fluid intake; include bran, whole grain products, and fresh vegetables in diet; encourage exercise (see Chapter 42). Administer prophylactic stool softeners on a regular basis.
Diarrhea	Constipation can add to discomfort. Diarrhea results from disease process (e.g., colon cancer), from complications of treatment or medications, or from fecal impaction caused by constipation.	Administer laxatives as necessary. Assess for fecal impaction (if sudden liquid stool occurs) and treat if required. Provide thorough perineal care if required. Administer antidiarrheals as needed. Confer with physician to change medication if possible. Provide low-residue diet.
Urinary incontinence	Incontinence results from progressive disease (e.g., involvement of spinal cord, reduced level of consciousness).	Protect skin from irritation or breakdown. Implement use of barrier creams to help protect skin integrity. Use disposable incontinence briefs if appropriate. Use indwelling urinary catheter or condom catheters if appropriate (see Chapter 43).
Inadequate nutrition	Nausea and vomiting can decrease appetite. Depression from grieving may cause anorexia.	Serve smaller portions and bland foods, which may be more palatable. Encourage intake of nutritional supplements. Allow home-cooked meals, which may be preferred by patient and gives the family a chance to participate in care.
Dehydration	As disease progresses, patient is less willing or able to maintain oral fluid intake.	Remove factors causing decreased intake; give antiemetics, and apply topical analgesics to oral lesions. Reduce discomfort from dehydration; provide mouth care at least every 4 hours; offer ice chips or moist cloth to lips.
Ineffective breathing patterns (e.g., dyspnea, shortness of breath)	Disease progression that involves lung tissue (e.g., progression of cancer, pneumonia, pulmonary edema) may affect breathing. Anemia reduces oxygen-carrying capacity. Anxiety increases oxygen demand. Fever increases oxygen demand.	Treat or control underlying cause. For example, in some cases of pulmonary edema, a diuretic may be appropriate and may temporarily relieve symptoms. Provide reassurance and comfort measures to the patient. Place patient in semi-Fowler's position, which will help. Maximize patient's oxygenation (e.g., place the patient in semi-Fowler's position or upright; provide supplemental oxygen; maintain a patent airway; reduce anxiety or fever). Administer medications such as bronchodilators, inhaled steroids, or narcotics and antianxiolytics to suppress cough, ease breathing, and alleviate apprehension. Administer antipyretics as needed. Promote comfort through measures such as removing some clothing and bedding.
Confusion, disorientation, and restlessness	These manifestations may be caused by hypoxia, metabolic changes, brain metastases, or medication side effects.	Ensure safe environment. Monitor patient frequently. Reorient the patient as needed. Administer medications as prescribed and as needed.

therapies and clinical practice standards are constantly evolving, you must keep your knowledge current.

Maintaining Dignity and Self-Esteem. The notion of dignity varies from patient to patient and between one circumstance and the next, and it is an overarching value or goal inherent in palliative care (Chochinov, 2006). Personal dignity may revolve around a person's positive sense of self-regard, is individualistic, and is closely linked with the patient's personal goals and social contexts (Chochinov, 2006). Dignity may also revolve around the extent to which patients feel valued and how they are treated by caregivers.

You can promote a patient's self-esteem and dignity by conveying respect for the patient as a whole person with feelings, accomplishments, and passions independent of the illness experience (Chochinov, 2006). Giving importance to autonomy, acceptance, resilience, and maintaining hope acknowledges individual personhood; it also strengthens the empathic, therapeutic communication between the patient, the patient's family, and yourself. Providing time for patients to share their life experiences, particularly about what has been meaningful, enables you to know patients better. Knowing patients then facilitates choice of therapies that promote patient decision making and autonomy.

For many patients, receiving spiritual comfort helps preserve dignity and self-esteem. Facilitating connections to a spiritual practice or community and supporting the expression of culturally held beliefs is very important. Patients may also benefit by being assured that some aspect of their lives may transcend death. In other words, the patient gains comfort from knowing that something of his or her life will continue after death. Participating in a life project such as making an audiotape or videotape for the family, writing letters, or keeping a journal can offer patients the comfort of knowing that something of their essence will survive (Chochinov, 2006). Chapter 27 further discusses some of the spiritual practices and religious rituals that can support people in need of spiritual comfort.

Basic to promoting self-esteem and dignity is attending to the patient's appearance and surroundings. Cleanliness, absence of body odours, attractive clothing, and personal grooming all contribute to a sense of worth. When helping a patient tend to bodily functions, you always show respect, even when the patient becomes dependent. It is important to keep the patient's immediate surroundings pleasant by opening curtains and letting light change from the bright of day to the dark of night. The quick removal of liquid stool or vomitus will help avoid unpleasant odours.

Disabilities experienced by the patient may threaten dignity, especially when caregivers take control of the patient's life. You allow the patient to participate in nursing care decisions (e.g., how and when to administer personal hygiene, diet preferences, and timing of nursing therapies). You keep the patient and family well informed about planned therapies, their purpose, and anticipated effects. It is also important to provide the patient with privacy during nursing care procedures and when the patient and family need time together.

Preventing Abandonment and Isolation. Many terminally ill patients are fearful of dying alone. Therefore, it is important for you to answer the call light quickly and to explain when staff will be giving care and performing assessments throughout the day and night. You should establish presence and use appropriate touch when performing care measures. You must be available to answer questions, even if

data are not needed, no further decisions are left to make, or no further curative interventions are available (Radwany et al., 2009). Patients may feel a sense of involvement when sharing a room and interacting with staff. Patients can share conversation and companionship with roommates and visitors. The choice of private or shared room should be discussed with the patient and family whenever possible.

Family is always considered as the unit of care in palliative care. If family members have difficulty accepting the patient's impending death, they may avoid visitation, exhibit denial, or express unrealistic expectations. When family members do visit, it is important to talk with them and keep them informed of the patient's progress. It may be useful to give family members helpful hints about what to discuss with patients. For example, you can help improve the family member's communication skills by role modelling attentive listening and offering reassurance. You should encourage the family to discuss activities other family members are involved in, reminisce about enjoyable times, and inquire about the patient's concerns. It is important for you to advocate for the patient to ensure that the patient does not become exhausted by visits. A useful strategy is to establish a schedule for family to be in attendance or to suggest family or friends visit two at a time. It is also helpful to find simple and appropriate care activities for the family to perform, such as feeding the patient, washing the patient's face, combing hair, and filling out the patient's menu. Older adults often become particularly lonely at night and may feel more secure if a family member stays at the bedside during the night. You should allow visitors to remain with dying patients at any time if the patient wants them. Also, you must know how to contact family members at any time if the patient requests a visit or if the patient's condition worsens.

Providing a Comfortable and Peaceful Environment. You keep a patient comfortable through frequent and regular repositioning, keeping bed linens dry, and controlling extraneous environmental noise. Pictures, cherished objects, cards or letters from family members and friends, and plants and flowers create an environment that is more familiar and comforting. You offer the patient frequent back, lower leg, and foot massage, or guided imagery exercises, and allow the patient time to listen to preferred types of music. A comfortable, pleasant environment helps patients relax, which promotes the ability to sleep and minimizes severity of symptoms.

Fear of Dying and Death. People are afraid of dying and death for many different reasons: the process of dying, with its associated pain and loss of dignity; not knowing what will happen after death; and dying before fulfilling dreams and goals. The intensity of the fear varies with each person and his or her circumstances, including age, culture, sex, personal experiences, family situation, social supports, and religious beliefs. Melvin and Oldham (2009) pointed out that nurses need to help patients realistically appraise these fears. Nurses also need to listen and understand as patients express their emotions.

Support for the Grieving Family. The family may be the primary caregivers when the patient chooses to die at home. Family members need support, and they benefit from being taught ways to care for their loved one (Box 28-9). Caring for a family member can be emotionally stressful and physically exhausting for the family caregiver. Not all families can manage care on their own. In the home setting, you provide the opportunity for the family to be temporarily relieved of duties so that they can rest. Such respite care is a resource

BOX 28-9 PATIENT TEACHING

Preparing the Dying Patient's Family

Objectives

- Improve the family's ability to provide appropriate physical care for the dying patient in the home.
- Improve the family's ability to provide appropriate psychological support to the dying patient.

Teaching Strategies

- Describe and demonstrate feeding techniques and selection of foods to facilitate the patient's ease of chewing and swallowing.
- Demonstrate bathing, mouth care, and other hygiene measures, and allow the family to perform return demonstration.
- Show the family a video on simple transfer techniques to prevent injury to themselves and the patient; help the family practise these techniques.
- Instruct the family on the need to take rest periods.
- Teach the family to recognize signs and symptoms to expect as the patient's condition worsens, and provide information on whom to call in an emergency.
- Discuss ways to support the dying patient, and listen to needs and fears.
- Solicit questions from the family, and provide information as needed.

Evaluation

- Ask the family members to demonstrate physical care techniques (e.g., turning, feeding, mouth care).
- Ask the family members to describe how they vary approaches to care when the patient has symptoms such as pain or fatigue.
- Ask the family to discuss how they feel about their ability to support the patient.

available through hospice programs, in which respite workers can come into the home, or a patient can go to a facility for a respite stay.

Families also need to be informed of home care, hospice, and community service options so they can choose among the resources available. The Saint Elizabeth Health Care Foundation in Canada has sponsored a free-of-charge publication called *Family Hospice Care: Pre-Planning and Care Guide*. This is a practical and informative resource written to help families meet the needs of terminally ill loved ones (van Bommel, 2006). Each province and health region has varying resources; therefore, you are required to know what is available to them in the individual family's jurisdiction. In some cases, families may need assistance and support in making the decision about placement in a health care facility.

You must keep the family informed so that they can anticipate the type of symptoms the patient will probably experience and the implications for care. You encourage family members to express their grief openly with the patient and to give the patient the opportunity to discuss any remaining concerns or requests. The family also needs personal time to share their concerns with you and to ask questions about treatment options, the course of the patient's disease, and the meaning of the patient's behaviours. It is wise for you to communicate news of the patient's impending death when the family is together, if possible. Family members can provide support for

one another. Convey the news in a private area, and be willing to remain with the family as needed. In some situations in which families are large or cannot all be together, it may be beneficial to have a designated family spokesperson or representative through whom information can be relayed.

It is important for you to educate the family regarding the signs of impending death. Tissue perfusion becomes impaired, which results in cool and clammy skin. Alterations in heart rate or rhythms, hypotension, and pooling of blood in dependent areas may occur. The extremities often have a mottled appearance. Breathing patterns may be impaired. Patients may exhibit shortness of breath or increased secretions. Later signs include increasingly longer and more frequent periods of apnea, alternating with hyperpnea; this pattern is known as Cheyne-Stokes respirations. Patients may exhibit alterations in level of consciousness and changes in behaviour; for example, disorientation and restlessness may occur. Urine output decreases, and incontinence may occur. In addition, periods of sleep increase, and eventually some patients may become unconscious as death nears.

In the hospital setting, you assist in planning a visitation schedule for family members to keep the patient and family from excessive fatigue. Young children should visit dying parents. During the final moments of a patient's life, you help the family to stay in communication with the patient through frequent visits, caring silence, attentive listening, touch, and telling the patient of their love. After the patient's death, you need to encourage the family to remain with the deceased for as long as they feel they need to. You are required to provide support and assist the family with decision making, such as notification of a funeral home or mortician, transportation of additional family members, and collection of the patient's belongings.

Hospice Care. Hospice care is an alternative care delivery model for terminally ill patients. It is one phase of palliative care. **Hospice** is not necessarily a facility but a concept for family-centred care designed to assist the patient in being comfortable and maintaining a satisfactory lifestyle until death. Hospice services are available in the home, hospital, stand-alone facilities, and long-term care settings. Availability and accessibility vary across Canada. Hospice care programs include the following components:

- Patient and family as the unit of care
- Coordinated home care with access to beds in available inpatient and long-term care facilities
- Control of symptoms (physical, sociological, psychological, and spiritual)
- Physician-directed services
- Provision of an interdisciplinary care team of physicians, nurses, spiritual advisors, social worker, and counsellors
- Availability of medical and nursing services at all times
- Bereavement follow-up after a patient's death
- Use of trained volunteers for frequent visitation and respite support

Canada's first hospice was established in Toronto in 1979. Casey House in Toronto and the John Gordon home in London, Ontario, provide hospice care for people dying from AIDS. Canuck Place, in Vancouver, was the first freestanding children's hospice in North America and provides a continuum of care that comprises three components: respite, palliative, and bereavement.

Your role in hospice care is to meet the primary wishes of the dying patient and to be amenable to individual desires of each

patient. You support a patient's choice in maintaining comfort and dignity. Whether the patient ultimately dies at home or in a health care facility, the patient's wishes are followed with the understanding that whatever his or her choice, it is made "for the good of all who are involved." When options are complicated by family needs, hospice professionals will try to work with the patients' wishes. A hospice program emphasizes palliative care with the patient and family as active participants. Patient care goals are mutually set, and all participants fully understand the options and desires of the patient. The hospice team attempts to meet the patient's desires and to encourage the family to stay within those guidelines. One or more bereavement visits are often made by the staff of the hospice team to the family even after the death of the patient to help the family move through the grieving process successfully.

Many patients prefer to die at home in a familiar setting, whereas others, not wishing to burden their families, choose to die in a hospital or long-term care facility. Alternatively, some families are ill-prepared or unable to care for a patient at home. It is important that the hospice team know the patient's preference. Many patients suffer physical ailments that prevent them from being cared for at home despite the willingness of family and friends to care for the patient. The health and welfare issues are viewed from a broader perspective than just the patient's desires. The concern for family needs is also taken into consideration by the hospice team.

A patient receiving hospice care may be hospitalized because of a change in condition or exacerbation of symptoms, and the health care team coordinates care between the home and inpatient setting. An effort is always made to keep patients at home for as long as possible. The family provides basic supportive care. However, if the family cannot meet all of the patient's needs, a nurse is available to coordinate and administer symptom management therapies. The goal of the interdisciplinary team is 24-hour accessibility as needed. As a patient's death becomes imminent, members of the hospice team are available to give support to the patient and family.

Care After Death. When a patient dies in a hospital setting, you provide **postmortem care**. It is important to care for the patient's body with dignity and sensitivity and in a manner consistent with the patient's religious or cultural beliefs. After death, the body undergoes many physical changes. For that reason, care must be provided as soon as possible to prevent tissue damage or disfigurement of body parts.

Hospitals are required to formulate policies and procedures that are based on current provincial and territorial laws to validate death, identify potential organ or tissue donors, and provide postmortem care. For transplantation of organs, the patient must be maintained in an intensive care unit on ventilatory and circulatory support until vital organs are harvested. The family must clearly understand that the patient is "brain dead" and that the equipment (i.e., ventilator and vasopressor medications) is not keeping the patient alive but keeping the physical body in a state so that the organs will not be damaged before being harvested.

Family support is crucial at the time of the patient's death. If family members are not present at that time, the assigned nurse (or another staff member who knows the family) makes contact with the family. If you are the assigned nurse, you inform the family of the death and respond to any immediate questions from the family. It is important that you find out from the family whether they will come to the facility to view

the deceased and to collect any personal belongings. Make a note of which family members will come and when. In some situations, family members may be too distraught to safely drive themselves and need to be encouraged to have someone else drive or to take alternative transportation. After a death, it is acceptable to lower the head of the bed, to straighten the body, and attempt to gently close the eyes and mouth. Once the family has arrived to view the deceased, it is beneficial, before they view the body, for you to explain to the family what they may expect to see. Typically, a deceased person has a peaceful expression (as facial muscles have relaxed); however, the body feels cool to touch and appears greyish-white. Within several hours, the body begins to stiffen as rigor mortis sets in. The body may have areas of pooled blood that appear bruised. The eyes and mouth may be partially open, but mucous membranes will appear dry. This appearance may be difficult for some family members to observe.

You can be very helpful in supporting families through the organ and tissue request process. It is important to provide a private area in which to discuss all issues with the family. The staff member designated to make a request, such as a formal transplant coordinator, a social worker, chaplain, or you, must offer the family clarification of what defines brain death because support systems must remain in place even after the patient is pronounced "dead" for vital organ retrieval (i.e., heart, lungs, kidneys, and liver). You reinforce explanations throughout the organ retrieval process. The family must know who legally can give final consent, the options for organ or tissue donation, any associated costs, and how donation will affect burial or cremation. Nonvital tissues such as corneas, skin, long bones, and middle ear bones can be harvested when the patient is proclaimed dead without artificially maintaining vital functions. If the patient did not make specific documented requests before death, the family must agree on organ and tissue donation. You should review the organ retrieval laws in the family's province or territory, as well as your institution's policy and procedure regarding the formal consent process.

Another topic that creates tension or anxiety is autopsy. The physician usually asks for permission for an autopsy, but nurses are often the professionals who answer questions and support the family's choices. It is very difficult to approach a grieving family with such a request; ideally, the topics of autopsy and donation are discussed before the patient's death. The value of an autopsy is that it may improve knowledge in the field of medicine or bring answers or clarification for the family. To help the living, the autopsy can lead to new therapies or new understanding of diseases. The more reasons you can think of to support organ donation, tissue donation, or autopsy, the more the family will be helped to realize the good that can be accomplished by either donation or research autopsy.

Patients' and families' cultural beliefs are very important in postmortem care (see Chapter 9). Maintaining the integrity of rituals and mourning practices helps families accept the patient's death and achieve an inner peace. The ethical decisions that surround a patient's death are based on the values of a culture. Health care providers must determine the makeup of a family network and which members should be involved in decisions such as organ donation and end-of-life care.

You are responsible for coordination of all aspects of care surrounding a patient's death. Box 28-10 summarizes the nurse's and physician's responsibilities for care of the body after death. It is important for you to be familiar with institutional policies and procedures that are established for

► BOX 28-10 Procedural Guideline

Care of the Body After Death

Delegation Considerations:

Care of the body after death can be delegated to unregulated care providers except in cases of organ or tissue donation. Check agency policy for which staff member is authorized to remove any invasive tubes or catheters.

Equipment:

Bath towels, washcloths, wash basin, scissors, shroud kit with name tags, bed linen, room deodorizer, documentation forms.

Procedure:

1. Physicians must complete the death certificate: cause of death, time when death was pronounced, therapy used, and actions taken. In some provinces such as British Columbia, nurses may pronounce the death but may not complete the death certificate. (This may not be the policy in all agencies. Follow your agency's policy.)
2. Physicians may request an autopsy, especially for deaths under unusual circumstances.
3. Trained staff members offer survivors the option of donating the organs or tissue of the deceased; personal, religious, and cultural needs should be included during this process.
4. Nurses work with sensitivity to preserve the patient's and family's dignity.
 - A. Check orders for any specimens or special orders needed by the physician.
 - B. Make arrangements for staff, spiritual advisor, or others to stay with the family while the body is prepared for viewing; find out whether survivors have special requests for viewing (e.g., shaving, a special gown, Bible in hand, rosary at the bedside).
 - C. Before shaving of male patient: Determine whether the family wishes the patient to remain unshaven if it was his custom to wear a beard. Determine whether patient's religion or culture has a preference regarding facial hair.
 - D. Remove all equipment, tubes, supplies, and dirty linens according to agency protocol. Exceptions to this process include organ donation (leave support systems in place), and sudden or unexpected deaths that necessitate coroner involvement or investigation (leave tubings and lines in situ, but cut them near the body and clamp them).
 - E. Cleanse the body thoroughly, apply clean sheets, and remove all trash from the room.
 - F. Brush and comb the patient's hair. Apply any personal hairpiece.
 - G. Position according to protocol: The eyes should be closed by gently holding the patient's eyelids closed for a few minutes; dentures should be in the patient's mouth to maintain facial alignment.
 - H. Cover the body with a clean sheet up to the chin with arms outside covers if possible.
 - I. Lower the lighting, and spray a deodorizer if possible to remove unpleasant odours.
 - J. Give the family the option to view or not to view the dead body; clarify that either option is acceptable.
 - K. If family members choose to view the dead body, go with them.
 - L. Encourage the family to say goodbye through both touch and talk.
 - M. Do not rush the goodbye process. Once the family is more comfortable, ask if they would like to be left alone. Remind them that they can call you if they need to.
 - N. Clarify which personal belongings should stay with the body and who will take personal items; documentation requires both a descriptor of the objects (i.e., rings, jewellery, electronics) and the name of each person who received them, with the time and date.
 - O. Do not discard items found after the family is gone; call the family and tell them what was found and ask who might pick it up. Descriptions of the articles help the patient's family make decisions accordingly.
 - P. Apply name tags according to protocol, such as on the wrist, on the right big toe, or outside a shroud.
 - Q. Complete documentation in the nursing notes. Documents vary, depending on the agency (see Box 28-11).
 - R. Remain sensitive to other hospitalized patients or visitors when transporting the body, such as covering the body with a clean sheet, temporarily and gently closing doors to patients' rooms, and watching to avoid visitors when moving the body to another part of the hospital or to the exit for the funeral home.
 - S. Follow all protocol and policies to meet all legal requirements in caring for the body.

postmortem care. Many of these practices also depend on the individuals' unique experiences and preferences.

The family becomes the primary patient when the actual death has occurred, and the shift of concern moves from the deceased patient to the living family. At this time, it is important to appropriately use the resources that are available. For example, pastoral care staff can be a helpful resource to assist the family even before the actual death, if no bereavement team is available. However, it is important to know whether the family chooses to have spiritual counsellors present. Some families prefer to grieve alone, whereas others may desire the support of other people. Social workers and counsellors can also offer assistance. If the family's expectations for support are unknown, any professional who assists the family can ask the simple questions and make suggestions for assistance.

Documentation of all the events surrounding a patient's death is important for avoiding misunderstandings and clarifying final events in a patient's life. Each facility's policies and procedures support legal guidelines that must be followed and accurately documented. Box 28-11 lists the content to be

documented about end-of-life care. Documentation validates the success of meeting goals identified for the patient or provides a justification for failure to meet any goals. Complete and accurate documentation offers a summary of activities that can become the focus for risk management or legal investigations.

A physician or coroner must sign some of the medical forms, but the registered nurse must record most of the forms. Gathering of information for the forms may be delegated to unregulated care providers, but you must chart the data in the nurse's notes. A licensed professional should witness the signing of forms.

In cases of legal matters, the family expects a clear, concise description of what occurred in the care of the patient at the time of death. Opinions must be avoided, and facts are stated in a nonjudgemental, objective manner. Provincial and territorial guidelines direct the type of information that is to be charted and when it is to be charted. Patients have the right to access their health records. Copies of parts of the chart can be given to family members upon written request and the

► BOX 28-11

Documentation of End-of-Life Care

The following items must be documented at the end of a patient's life:

- Time of death and actions taken to prevent death, or cardiac arrest record if applicable
- The name of the person who pronounced the patient's death
- Any special preparation and type of donation, including time, staff, and company
- The name of the family member or friend who was called and who came to the hospital: donor organization, morgue, funeral home, chaplain, and individual family members making any decisions
- Personal articles left on the body and taped to skin, or tubes left in
- Personal items given to the family: specific names and descriptors of items
- Time of discharge and destination of the body
- Location of name tags on the body
- Special requests made by the family
- Any other statements that might be needed to clarify the situation

approval of the physician and hospital (see your employer's guidelines). You must understand and uphold the legal guidelines of documentation at all times (see Chapter 15).

The Grieving Nurse. When you have cared for a patient for a period of time, it is possible to have deep personal feelings of loss and sadness when the patient dies. It is common for nurses to want to hold the hand of the patient who is dying. By being present at the time of the patient's death, you are able to "let go."

You can attempt in many ways to cope with the loss of a dying patient. Attending the viewing at the mortuary or funeral is one way to say goodbye. Writing a letter of sympathy to the family can prove helpful. Some agencies routinely send out sympathy cards from the interdisciplinary team, in which you can write an individual note. It is natural for you to go through the grieving process. When you work in an area in which multiple losses occur, it is easy for bereavement overload to develop unless you have ways to process grief. You might feel frustration, anger, guilt, sadness, or anxiety. Often nurses seek out other nurses or health care providers to discuss their own grief (Figure 28-5). It is important for you to develop your own support systems that allow time away from the care setting and provide opportunities to share personal feelings. Stress management techniques (see Chapter 29) can help restore a nurse's energy and continued enjoyment in caring for patients. Your self-care is crucial for your survival and recovery from loss, not only for your sake but also for the sake of future patients. Interdisciplinary team debriefings regarding complex or ethical issues are valuable in helping you cope with loss. Nurse managers and administrators have a responsibility to ensure that the working environment is supportive (Rollings, 2008).

❖ Evaluation

Patient Care

You care for patients and families at every phase of the grief process. This requires you to remain aware of signs and

Figure 28-5 Nurses benefit from support of colleagues during their time of loss.

symptoms of grief, even when patients are not specifically seeking care directly related to a loss. These signs and symptoms help you evaluate whether a patient is able to deal with a loss and progress through the grief process. Critical thinking ensures that the evaluation process is thorough and relevant to the patient's situation (Figure 28-6).

To determine the effectiveness of nursing interventions, you must refer to the goals and expected outcomes established in the plan of care. By comparing actual patient behaviours with expected outcomes, you evaluate the patient's health status and whether the plan needs to be revised. For example, if the goal is to have the patient communicate a sense of hope with family members, you evaluate the verbal and nonverbal communication process for cues related to hope. The patient's responses indicate whether new therapies are needed or whether existing therapies should be revised. You continue to evaluate the progress of the patient, the effectiveness of interventions, and the interactions between the family and patient. It is important for the patient and family to share experiences and be active participants in the evaluation process.

Patient Expectations

The patient expects individualized care, including relief of symptoms, preservation of dignity, and support of the family to maximize quality of life. The success of the evaluation depends partially on the bond that you form with the patient.

Figure 28-6 Critical thinking model for loss, death, and grieving evaluation.

If the patient does not trust you, he or she is not likely to share personal expectations or desires with you. It becomes important for you to take the time to talk with the patient and learn whether expectations are being met. The following are examples of questions that will validate whether patient expectations have been achieved:

- "Am I helping you in the way you have hoped?"
- "Would you like me to assist you in a different way?"
- "Do you have a specific request that I have not yet met?"
- "What is most important for us to do for you at this time?"
- "Are we dealing with your problems in a timely manner?"

Through communication and evaluation, you continue to determine whether outcome criteria were met to support the goals of care. It is often easy to evaluate the patient's needs, but evaluating the family's needs is more complex. Once rapport is established, you must be vigilant to avoid problems that threaten that rapport.

✦ KEY CONCEPTS

- When caring for patients who have experienced a loss, you facilitate the grief process by assisting survivors in feeling the loss, expressing the loss, and moving through the tasks of the grief process.
- Loss comes in many forms, depending on the values and priorities learned within a person's sphere of influence, which includes family, friends, society, and culture.

- The type of loss and the perception of the loss influence the degree of grief a person experiences.
- Death is difficult for the dying person, as well as for the person's family, friends, and caregivers.
- Survivors go through a bereavement period that is not linear; rather, a grieving individual will move back and forth through a series of stages, tasks, or both many times, possibly over a period of several years.
- Several theorists have formulated stages of the grieving process and a series of tasks for survivors to successfully complete their bereavement and adapt to life with a loss.
- Your knowledge of the types of grief enables you to implement appropriate bereavement therapies.
- The way an individual perceives and responds to a loss is influenced by development, psychosocial perspectives, socioeconomic status, personal relationships, the nature of the loss, culture, and spiritual beliefs.
- Nursing interventions involve reinforcing patients' successful coping mechanisms and introducing new coping approaches, such as the promotion of hope.
- When assessing patients in grief, you do not assume how or whether patients experience grief or whether a particular behaviour indicates grief; rather, you allow patients to share in their own way what is happening.
- You must assess the terminally ill patient's and family's wishes for end-of-life care, including the preferred place for death, the level of life-sustaining measures to use, and expectations regarding pain and symptom management.
- You develop a plan of care by integrating patients' resources such as physical energy and activity tolerance, supportive family members, spiritual faith, and methods for coping.
- You establish a caring presence and use therapeutic communication strategies that enable patients to discuss their loss and find ways to manage it.
- Palliative care enables patients to make more informed choices, better alleviate symptoms, and have more opportunity to manage unfinished business.
- You can promote a patient's self-esteem and dignity by conveying respect for the patient as a whole person.
- Hospice is not a facility but a concept for family-centred care designed to assist the patient in being comfortable and maintaining a satisfactory lifestyle until death.

✦ CRITICAL THINKING EXERCISES

1. Mr. Singh visits the community health clinic and tells you, "I don't know what's wrong with me. I lost my wife six months ago and I still get angry that God let her die. I still miss her so much. I have been going out with friends, but I just don't enjoy it that much. Sometimes I wake up at night and I think my wife is still here. What is wrong with me? I thought I would be feeling better by now." How could you respond to Mr. Singh?
2. You are assigned to care for Mrs. Nester. She has bone cancer and has experienced ongoing deep pain in her back and hips, with some discomfort also in her lower extremities. Discuss the management of pain for Mrs. Nester.
3. A nursing colleague is discussing her patient with you. She says, "My patient is a 48-year-old man with a degenerative neurological disease. The disease is progressive. He is having trouble walking and taking care of his daily needs. The only thing I can do is assist him with bathing, feeding, and walking. He really is not a candidate yet for palliative care." What would be your response to your colleague?

✦ REVIEW QUESTIONS

1. A child is grieving over the loss of a pet. This is an example of
 1. An actual loss
 2. A perceived loss
 3. A situational loss
 4. A maturational loss
2. A middle-aged man comes to a community clinic for his annual flu shot. In the discussion, you learn that he still works at a local law firm. However, he has recently lost two important cases, and his boss has been pressuring him "to turn it around." The patient may be experiencing
 1. An actual loss
 2. A perceived loss
 3. A situational loss
 4. A maturational loss
3. The community health nurse's job is to provide grief counseling for the residents of a community in which a major flood has occurred. The loss associated with flooding is best described as
 1. An actual loss
 2. A perceived loss
 3. A situational loss
 4. A maturational loss
4. A patient has received a diagnosis of terminal brain cancer. When you visit him during rounds, he asks you whether the cancer could have been caused by something he ate or by exposure to some chemical toxin. The patient is probably experiencing
 1. Bowlby's phase of numbing
 2. Kübler-Ross's stage of acceptance
 3. Worden's tasks of emotionally relocating
 4. Bowlby's phase of disorganization and despair
5. According to Kübler-Ross's stages of dying, a patient may feel overwhelmingly lonely and withdraw from interpersonal interaction during this phase:
 1. Denial
 2. Anger
 3. Bargaining
 4. Depression
6. Since the death of his wife, the patient has assumed full responsibility for the care of his children. He has noticed over the past few weeks that friends are calling less often. He is most likely in which of the following phases of mourning?
 1. Anticipatory grieving
 2. Worden's task 3 of mourning
 3. Kübler-Ross's phase of bargaining
 4. Bowlby's phase of disorganization and despair
7. Which of the following is one of the most common and difficult issues faced by older bereaved spouses?
 1. Adjusting to physical problems
 2. Overcoming mental health problems
 3. Completing the tasks of daily living
 4. Managing finances
8. "Patient will express hopefulness that cancer treatment will control symptoms" is an example of
 1. A goal
 2. An intervention
 3. A plan
 4. An expected outcome
9. A 16-year-old patient has been admitted to the intensive care unit after suffering a closed-head injury. The patient is soon declared brain dead. The physician and nurse are preparing to approach the family to consider donation of the patient's heart and lungs. When working with families in this situation, it is important to explain that
 1. The ventilator is being used to prevent brain death
 2. The ventilator maintains organ perfusion until time for harvesting
 3. Tissues such as corneas can be harvested only if the patient remains ventilated
 4. Organ donation can occur only if the patient has made a request to donate organs in the past
10. Which of the following types of care allows patients to make more informed choices, achieve better alleviation of symptoms, and have more opportunity to manage unfinished business?
 1. Acute care
 2. Mourning care
 3. Palliative care
 4. Terminal care

Stress and Adaptation

Written by Marjorie Baier, RN, PhD, and Kathy Hegadoren, RN, PhD

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Describe how stress is conceptualized.
- Define the key biological systems involved in stress responses.
- Describe how overwhelming stress or chronic stress can affect health.
- Differentiate acute stress disorder and post-traumatic stress disorder.
- Discuss the integration of stress theory with nursing theories.
- Formulate nursing diagnoses from assessment data.
- Describe stress management techniques beneficial for coping with stress.
- Discuss the process of crisis intervention.
- Develop a care plan for patients experiencing stress.
- Discuss how stress in the workplace can affect health care providers.

Stress: Everyone has experienced it, but the term **stress** is difficult to define and is often loosely used. It has been used to describe a stimulus, a process, a response, and a state, which leads to confusion and ambiguity (Le Moal, 2007). In this chapter, the term **stressors** is used to describe events that activate stress response systems: that is, act as stimuli. This activation of multiple biological systems and psychological schemas has a collective goal of maintaining a state of dynamic equilibrium. Stressors can arise in the external environment and range from motivational prompts, such as taking a school examination, to devastating personal events, such as a life-threatening illness, a motor vehicle crash, a sexual assault, or a natural disaster (e.g., an earthquake or a tornado). Internal stressors, such as hunger or infection, can also activate stress response systems. Behavioural responses to stressors presumably reflect the activation of numerous biological systems. Behavioural responses can

change over time, inasmuch as previous stressful experiences and individual contextual factors can produce **adaptation** in stress response systems. Among animals, biological systems help alert the animal to some type of threat in the environment and prepare it to mount a defence. These systems also turn off when the threat is past. For humans, in addition to acute threats to body integrity, psychological well-being and sense of self-worth can be threatened. Physical and psychological health can be severely affected by serious or chronic stressors, and these effects can be long-standing and pervasive. It is important for health care providers to understand conceptual frameworks that have been developed to explain the relationship between stress (overwhelming or chronic) and health.

Conceptualizations of Stress

Physiological Conceptualizations

Walter Cannon was one of the pioneers of the early twentieth century who laid the groundwork for regulatory physiology and concepts of adaptation. He demonstrated that the sympathetic-adrenal-medullary (SAM) system acted to maintain homeostasis of the internal environment. He first coined the term **fight-or-flight response**, in 1915, to describe an animal's response to threats through the activation of the SAM system (Figure 29-1; Le Moal, 2007). Hans Selye, another pioneer, focused on maladaptation and the pathology of stress. He demonstrated the existence of a biological stress syndrome, which he called the **general adaptation syndrome** (Selye, 1974; Figure 29-2). This three-stage syndrome occurs in response to serious stressors. The first stage is the **alarm reaction**, analogous to Cannon's fight-or-flight response to stress. In this stage, complex physiological changes help the organism mobilize energy and react to the stressor. The second stage of the general adaptation syndrome is the **resistance stage**. During

resistance, the organism maintains arousal while the body works to defend against and adapt to the stressor and maintain homeostasis. Should the stressors continue for an extended period, organisms use up their finite ability to adapt, and they enter a third stage of the adaptation syndrome, called the **exhaustion stage**. This is a pathological state in which organisms start showing diverse health consequences, which may eventually result in death. Selye was also the first to emphasize the role of the pituitary-adrenal axis in the pathological processes of stress.

At this point, two systems for stress were proposed: (1) the SAM system for behavioural fight-or-flight responses to stress and immediate adaptation and (2) the pituitary-adrenal axis for maintaining homeostasis. The concept of the pituitary-adrenal axis was expanded to the hypothalamic-pituitary-adrenal (HPA) axis; this axis is thought to mediate a bidirectional brain-body communication during physiological and psychological stress and is activated to promote homeostasis and to adapt to threatening or stressful situations (Engelmann & Ludwig, 2004). Bruce McEwan (2007), elaborating on the concept of **homeostasis** (the return of systems to a stable set point), used the term **allostasis** to describe how serious stressors can change physiological set points through adaptation. In this way, organisms are readied to respond and adapt to future stressors, but maintaining this state of readiness has an energy cost. This cost is termed **allostatic load**, which refers to the physiological burden of repeated stressors and enduring a heightened stress response system. When this load becomes too great, stress responses change from adaptation to health problems and stress-related disorders.

Psychological Conceptualizations

In addition to physiological models of stress and stress responses, cognitive approaches to stress were also studied. The general adaptation syndrome and fight-or-flight responses to stress did not explicitly take into account perceptions and appraisals of stress in humans. Researchers began to look at the relationship between the person and the environment. The roles of perception and appraisal in stress responses are integral in the framework of stress proposed by Richard Lazarus. Lazarus (1999) maintained that a person is under stress only if the person evaluates the event or circumstance as personally significant. **Appraisal** of an event or circumstance is an ongoing perceptual process (Aguilera, 1998). Evaluating an event for its personal meaning is called **primary appraisal**. If as a result of primary appraisal the person identifies the event or circumstance as a harm, loss, threat, or challenge, the person experiences stress. If stress is present, **secondary appraisal** focuses on possible coping strategies. **Coping** is the active process of managing taxing circumstances, expending effort to solve personal and interpersonal problems, and seeking to master, minimize, reduce, or tolerate stress or conflict. Balancing factors contribute to restoring equilibrium.

If previous ways of coping are not effective, a **crisis** may occur, in which the person faces a turning point in life and the person must change. Caplan (1981) distinguished two types of crises: those associated with changing developmental levels, or **developmental crises**, and **situational crises**. Examples of developmental crises could be related to mastering developmental tasks as an individual (independence in adolescence) or as a family (children leaving home, caregiving to elderly parents). Examples of situational crises could include natural disasters like floods or famine, the end of an intimate

Figure 29-1 Fight-or-flight response.

Figure 29-2 General adaptation syndrome. ACTH, Adrenocorticotrophic hormone; ADH, antidiuretic hormone.

relationship, or loss of work transportation through a motor vehicle crash. The frame of reference for a crisis is the viewpoint of the person experiencing the crisis. According to Aguilera's (1998) crisis theory, the vital questions for a person in crisis are "What does this mean to you?" and "How is it going to affect your life?" A basic assumption of crisis theory is that a person can either advance or regress as a result of a crisis, depending on how the crisis is managed. Feedback cues lead to ongoing reappraisals of original perceptions. Therefore, coping behaviours constantly change as new information is perceived.

Later work in the important role of appraisal and perception focused on the contribution of age and gender to responses to stressful events. Coping strategies, meaning attached to events, and responses to stressors change with age (Nosek et al., 2010). Gender differences may be conceptualized as an interaction between biologically based sex differences and an individual's social context (Desbonnet et al., 2008; Kimerling et al., 2000). Women and men may perceive a stressor differently, may attach different meanings to that stressor, and thus may have different responses and reactions (Davis et al., 1999;

Liu & Alloy, 2010). For example, Taylor (2006) has theorized that women more often show nurturing and support-seeking behaviours in response to stress, rather than fight-flight behaviours.

In summary, individual differences in response to stressors can be affected by previous vulnerabilities and experiences, coexisting health problems, age, gender, allostatic load, and coping resources. Psychological and biological conceptualizations are not mutually exclusive. Indeed, the integration of the various frameworks help explain the complexity of the relationship between stress and health.

Stress Response Systems

Sympathetic-Adrenal-Medullary System

Activation of the SAM system results in increased heart rate, diversion of blood from the intestines to the brain and skeletal muscles, increased blood pressure, bronchodilation and increased respiratory rate, and increases in blood glucose levels (Chrousos et al., 1988; Selye, 1991). All these changes are meant to prepare for fight-or-flight responses. A stressor

activates specific cells in the brain stem that release norepinephrine into the bloodstream. Norepinephrine stimulates the adrenal medulla to release epinephrine. Epinephrine produces the cardiovascular, respiratory, and metabolic changes and the heightened awareness or alertness. Chronic stimulation brings about a chronic arousal state, with sleep disturbance, edginess and irritability, gastrointestinal upset, and increased startle responses. Brain areas that are involved in this stress response system include the following:

- **Reticular formation:** This is a small, integrative cluster of neurons in the brain stem and spinal cord that continuously monitors the physiological status of the body through connections with sensory and motor tracts. For example, certain cells within the reticular formation can cause a sleeping person to regain consciousness or increase the level of consciousness when a need arises.
- **Limbic system:** This is another integrative cluster of neurons that interconnect several parts of the brain that is involved in processing strong emotional experiences. Fear and perceived threat will cause increased activity within this system.
- **Midbrain and pons:** The midbrain joins the lower part of the brain stem and the spinal cord with the higher part of the brain and acts as a reflex centre for certain auditory, visual, and postural stimuli. The pons mainly relays impulses to and from the medulla oblongata to other parts of the brain and the peripheral nervous system, and it also controls the rate and depth of breathing.
- **Medulla oblongata:** This brain region controls vital functions necessary for survival, including heart rate, blood pressure, and respiration. Impulses travelling to and from the medulla oblongata can increase or decrease these vital functions. For example, heart rate is regulated by sympathetic or parasympathetic nervous system impulses travelling from the medulla oblongata to the heart. The rate increases in response to pulses from sympathetic fibres and decreases with impulses from parasympathetic fibres.

Hypothalamic-Pituitary-Adrenal Axis

Activation of the HPA axis results in the release of a cascade of hormones (Dunn, 1989). A stressor activates the hypothalamus to release a corticotrophin-releasing hormone (CRH). This hormone activates receptors in the anterior pituitary, which signals the release of adrenocorticotrophic hormone (ACTH) into the bloodstream. ACTH interacts with its receptors in the adrenal cortex to release glucocorticoids. In humans, the major glucocorticoid is cortisol. Cortisol has effects similar to those of epinephrine, contributing to the increase in heart rate and blood pressure, causing shunting of blood to skeletal muscles, and increasing the availability of glucose in the bloodstream. This stress response system is tightly controlled by negative feedback, whereby rising cortisol levels activate receptors in the hypothalamus and the pituitary gland, shutting off further release of CRH and ACTH (Brunello et al., 2001). Other brain chemicals, such as β -endorphin (Kageyama et al., 2011), arginine vasopressin (Yayou et al., 2009), and oxytocin (Oliff et al., 2010) are also involved in the regulation of the HPA axis.

This part of the endocrine system interacts with other parts that regulate sex hormone levels, thyroid hormones, electrolyte and fluid balance, and insulin release. Therefore, overwhelming or chronic stressors can have diverse and complex impacts on health. The following brain areas are involved in this stress response system:

- **Hypothalamus:** This region of the brain is involved with many basic physiological processes, including appetite, sexual drive, sleeping, motor activity, and mood states (all of which are affected by stress). The hypothalamus is highly interconnected with many other areas of the brain. Dysregulation of the hypothalamus is thought to be involved in depression.
- **Pituitary gland:** This small gland, attached to the hypothalamus, produces and releases hormones that control vital functions. It is divided into the anterior and posterior portions. The anterior pituitary releases stress-, thyroid-, growth-, and reproduction-related hormones, whereas the posterior pituitary releases hormones related to electrolyte and water balance, as well as oxytocin. Both the pituitary gland and the hypothalamus can produce endorphins. **Endorphins** are hormones that produce a sense of well-being and reducing pain (Lazarus, 1999).
- **Adrenal glands:** One of these glands rests atop each kidney, and they are fundamental to stress responses. Each is composed of two very different regions. The outer region, or cortex, is where glucocorticoids such as cortisol are produced and released, and the inner region, or medulla, is where epinephrine is produced and released.

Stress and the Immune System

Physiological responses to stress also include immunological responses, although the mechanisms through which stress affects the immune system are not fully understood (Aldwin, 2000; Box 29-1). The immune system differentiates between self and non-self material, so that, under normal conditions, one's own cells are not treated as threats in the way that bacteria, viruses, parasites, or toxins are treated. An antigen on the surface of bacteria cells identifies them as invaders. After being exposed to a particular antigen, the immune system remembers how to respond to that antigen and is prepared to respond with antibodies when the same antigen appears at a later time. Autoimmune illnesses like multiple sclerosis, fibromyalgia, or insulin resistance can occur when the immune system misinterprets the body's own cells as foreign. Glucocorticoids are powerful anti-inflammatory agents and play a role in the

Factors Influencing the Response to Stressors

Aspects of a Stressor That Influence the Stress Response

- Intensity
- Scope
- Duration
- Number and nature of other stressors
- Past exposure to serious stressors
- Predictability

Characteristics of the Individual That Influence the Stress Response

- Age
- Gender
- Perception of personal control or inescapability
- Availability of social supports
- Feelings of competence
- Cognitive appraisal

cascade of homeostatic immune responses that are activated by infection or inflammation and clinical depression. Dysregulation or chronic activation of the SAM system and the HPA axis may increase the risk of stress-related mental illnesses, as well as cardiovascular disease, insulin resistance (which in turn can increase risk for type 2 diabetes), metabolic syndromes, and autoimmune illnesses.

The Relationship Between Type of Stressor and Health

Selye (1974) identified two types of stress: **distress**, or damaging stress, and **eustress**, or stress that protects health. Eustress is motivating energy, such as happiness, hopefulness, and purposeful movement (Varcarolis, 2002). Eustress is a positive, healthy adaptation to stressors in daily life. In reference to this concept, Selye (1974) wrote the book *Stress Without Distress*. However, Aldwin (2000) wrote that the idea of healthy stress is controversial because it is difficult to tell whether a person has benefited from stress or is coping by denying the stress in some way.

Distressing events can be categorized in many ways, including work stressors, family stressors, chronic stressors, acute stressors, daily hassles, trauma, and crisis: “Work and family stress interact, family being the background for work stress, and work the background for family stress” (Lazarus, 1999). Women who have preschool children, for example, may experience full-time work as stressful when their child cannot go to day care because the child is ill and their husband’s job involves extended periods away from home. It is difficult to categorize some events, like the horrific devastation and loss of life experienced as a result of the March 2011 earthquake in Japan, and to predict what long-term health implications there will be for the Japanese population. Chronic stress can arise also from stressful roles, such as being a caregiver for a spouse with Alzheimer’s disease, or persistent physical or psychological conflict. Another example of chronic stress is living with a long-term illness. Conversely, acute stress is provoked by time-limited events that are threatening for a relatively brief period. In the context of chronic or acute stress, daily hassles, such as commuting to work, maintaining a home, social and personal interactions, and managing money, can become more difficult to manage. **Trauma** can refer to any physical damage to the body or in psychological terms can refer to feelings of fear, threat, and persistent reliving after witnessing or experiencing an emotionally painful, distressful, or shocking event(s). Severe stressors such as natural disasters or interpersonal events such as family violence or child maltreatment are often considered traumatic events; however, as in other types of stressors, perception plays a major role in the individual’s response to such events. Indeed, for some people, serious stressors can lead to positive change or personal growth, leading in turn to greater self-knowledge, improved coping skills, stronger social ties, and positive changes in values and perspectives (Hyer & Sohnle, 2001; Wendt et al., 2011). There is an emerging body of knowledge regarding positive change, called **post-traumatic growth** and defined as “positive psychological change experienced as a result of the struggle with highly challenging life circumstances” (Tedeschi & Calhoun, 2004).

Stress-Related Disorders

Prolonged exposure to a serious stressor or an acute stressor that overwhelms the ability to cope can lead to stress-related

* BOX 29-2 RESEARCH HIGHLIGHT

Understanding Risks for Developing Psychological Distress

Research Focus

When caring for patients who have experienced traumatic events such as motor vehicle crashes, assaults, and industrial accidents, nurses focus first on life-threatening effects of the trauma. However, other consequences of trauma, such as psychological distress, may not be immediately evident. You need to be aware of risk factors for anxiety, depression, acute stress disorder, and post-traumatic stress disorder after trauma and help your patient understand some common responses to such events, how many acute stress symptoms fade with time, and what symptoms should be reported to a health provider.

Research Abstract

The purpose of Joy et al.’s (2000) study was to describe pretrauma characteristics of people who experienced significant psychological distress shortly after physical injury. Individuals who had received treatment in the emergency department were contacted and asked to complete three questionnaires: the Post-traumatic Stress Disorder Scale, the Impact of Event Scale (IES), and the Hospital Anxiety and Depression Scale. A fourth questionnaire, the Abbreviated Injury Scale, was completed by the researchers on the basis of a medical record review. Significant psychological distress was documented in 152 people (87 women and 65 men) of all the people receiving emergency treatment. Overall, the people identified with distress reported very little functional impairment and a high level of contentment before the traumatic event. Most of their injuries were relatively minor and not life-threatening. However, 141 (93%) of the subjects showed evidence of post-traumatic stress disorder (PTSD). The IES revealed that the subjects were experiencing high levels of trauma-related distress. The researchers examined the relationship between pretrauma variables and the total score on the IES. The pretrauma factors of being unemployed and having experienced previous trauma were shown to be important contributors to the total IES score. The researchers concluded that (1) trauma perceived as mild by nurses and other health providers can nonetheless result in severe stress, anxiety, and depression for the patient; (2) high functioning before a traumatic event does not protect the patient from developing PTSD symptoms; and (3) pretrauma unemployment can contribute to psychological distress after a traumatic injury.

Evidence-Informed Practice

- Regardless of the severity of trauma or previous level of functioning, patients who have experienced a traumatic injury are at risk for developing PTSD.
- Nurses must monitor the patient’s perception of the meaning and impact of a traumatic injury, regardless of the apparent severity of the trauma.
- Two risk factors for developing PTSD after a traumatic injury are unemployment before the trauma and previous trauma.

Reference: Joy, D., Probert, R., Bisson J. I., & Shephard, J. P. (2000). Post-traumatic stress reactions after injury. *Journal of Trauma*, 48(3), 490–494.

disorders (Box 29-2). However, even if an individual’s stress-related symptoms do not meet full criteria for a stress disorder, it is important to recognize that those symptoms may have a significant impact on the individual’s functioning and their relationships with others. If interventions are not implemented, these symptoms can decrease quality of life and increase the

risk of developing the full disorder. Early emerging stress-related symptoms include poor sleep, tension and jitteriness, and inability to concentrate, to a degree that day-to-day activities are affected.

Although stress-related psychiatric disturbances are usually considered to be acute stress disorder and post-traumatic stress disorder (PTSD), these are only two potential health outcomes. It is important to recognize the diversity of health effects from serious stressors. Indeed, clinical depression, chronic pain syndromes, somatization disorder, and irritable bowel syndrome have all been linked to chronic stress (Blackburn-Munro & Blackburn-Munro, 2001; Matthews et al., 2001). Health providers need to perform thorough, multifaceted assessments to identify the full range of health effects.

Acute Stress Disorder. Acute stress disorder is limited to the month after experiencing, witnessing, or being confronted with a traumatic event; the reaction is one of intense fear, helplessness, or horror (American Psychiatric Association, 2000). Other criteria of acute stress disorder are as follows: (1) The patient displays at least three acute dissociative symptoms; (2) the patient has at least one recurring symptom (intense memories, **flashbacks** [recurring, intensely vivid mental images of a past traumatic experience], or distressing dreams); (3) the patient displays marked avoidance of stimuli that arouse memories of the trauma; (4) the patient shows marked hyperarousal; and (5) these symptoms emerge between two days and four weeks after the traumatic event (Hyer & Sohnle, 2001). These symptoms must have a significant effect on the individual's occupational, social, or personal functioning to meet full criteria for acute stress disorder. Examples of traumatic events that lead to acute stress disorder are motor vehicle crashes, natural disasters, violent personal assault, emergency service work experiences, and military combat. Nurses are also not immune to acute stress disorder. Treatment usually focuses on symptoms: to aid in sleeping and to relieve the jitteriness and irritability. If the trauma-related symptoms persist longer than one month, the individual will likely meet the criteria for post-traumatic stress disorder.

Post-Traumatic Stress Disorder (PTSD). Symptoms of **post-traumatic stress disorder (PTSD)** are more persistent, having endured for at least one month (American Psychiatric Association, 2000). The symptom clusters are similar to those of acute stress disorder, with less emphasis on dissociative symptoms (Breslau & Kessler, 2001). The diagnosis of PTSD was formulated from research with men returning from the Vietnam War and was first thought to be quite rare. Ongoing community-based studies showed it to be more prevalent, with lifetime prevalence rates of 6.8% (Brunello et al., 2001). Treatment guidelines for PTSD have been published and include multimodal interventions with drug therapy and targeted psychotherapy (Forbes et al., 2010).

Nursing Knowledge Base

Nurses have proposed theories related to stress and coping. Because stress plays a role in vulnerability to disease, symptoms of stress often necessitate nursing intervention.

Nursing Theory and the Role of Stress

Neuman's (1995) systems model is based on the concepts of stress and reaction to stress. Nurses are responsible for developing interventions to prevent or reduce stressors on the patient or to make them more bearable for the patient (Neuman,

1995). Because Neuman's model is a systems model, it is applied not only to understand patients' individual responses to stressors but also to understand families' and communities' responses. All systems experience multiple stressors, each of which has a differing potential to disturb the person's, family's, or community's dynamic balance. Every person has developed a set of responses to stress that constitute the "normal line of defence" (Neuman, 1995). This line of defence helps maintain health and wellness. However, when "physiological, psychological, sociocultural, developmental, or spiritual influences" are unable to buffer stress, the normal line of defence is broken, and disease can result. Neuman's systems model coincides with Selye's (1974) general adaptation syndrome and McEwan's (2007) concept of allostatic load.

Neuman's (1995) systems model stresses the importance of accuracy in assessment and interventions that promote optimal wellness through the use of primary, secondary, and tertiary prevention strategies. According to Neuman's theory, the goal of primary prevention is to promote patient wellness by stress prevention and reduction of risk factors. Secondary prevention occurs after symptoms appear. You help the patient determine the meaning of the illness and stress, and you find resources available to handle them. Tertiary prevention begins when the patient is becoming more stable and recovering. At the tertiary level of prevention, you support rehabilitation processes involved in healing, moving the patient back to wellness, and the primary level of disease prevention.

In their health promotion model, Pender and colleagues (2002) proposed that health promotion is directed toward increasing the level of well-being of an individual or group. Conversely, primary, secondary, and tertiary prevention (health protection) focus on avoiding negative events. Pender et al. considered stress reduction strategies important to reduce threats to well-being, to help people fulfill their potential, and to shape and maintain health behaviours. To change behaviour, the patient must initiate the change and behave differently in interactions. On the basis of core assumptions regarding the capability and desire of people to be healthy, Pender et al. suggested strategies for prevention and health promotion related to stress management.

Situational, Maturational, and Sociocultural Factors

Multiple factors affect the types of potential stressors and coping mechanisms. Age is one; for example, adolescence, adulthood, and old age bring different stressors (Andersen & Teicher, 2008). Appraisal of stressors, amount and type of social support, and coping strategies are other factors that affect appraisal of stressors, as are previous life experiences (Aguilera, 1998).

Situational Factors. Situational stress can arise from the person's current circumstances, such as moving, changing jobs (stressful job changes include promotions, transfers, downsizing, restructuring, and changes in supervisors and/or responsibilities), and adjusting to a chronic illness or condition. Common diseases and conditions that can be exacerbated by stress are obesity, hypertension, diabetes, depression, asthma, and coronary artery disease. Being a family caregiver may also cause situational stress, although the source of stress may be not necessarily the caregiving but other factors in the caregiver's life, such as work, finances, or lack of respite (Merluzzi et al., 2011). Spouses and other family members also experience stress when a loved one is ill (Box 29-3).

* BOX 29-3 RESEARCH HIGHLIGHT

Spousal Support for Psychological Distress

Research Focus

Holistic nursing care includes the patient's family. Family members, especially the spouse, influence the patient's recovery from cardiac disease and surgery. More information is needed about stress experienced by spouses of patients in cardiac rehabilitation and interventions to help spouses cope with stress.

Research Abstract

The purposes of Chung et al.'s (2010) study with patients with heart failure were (1) to examine differences between caregivers with or without depressive symptoms in patients' characteristics and caregiver functional status, caregiving burden, and perceived sense of control, and (2) to determine factors that predicted depressive symptoms of caregivers, controlling for gender and age. Patients and their primary caregivers were recruited from outpatient clinics. Both were asked to independently fill out questionnaires to assess presence of depression symptoms, functional status, caregiving burden, and perceived sense of control. Twenty-eight percent of caregivers who had depressive symptoms had poorer functional status, lower perceived control, and higher caregiving distress and spent more time with caregiving tasks than did caregivers with no depressive symptoms. The authors suggest that both the patient and their caregivers may benefit from interventions aimed at the caregivers' depressive symptoms.

Evidence-Informed Practice

- Spouses of patients with chronic heart problems could benefit from the following interventions:
- Stress-management techniques, such as relaxation training, assertiveness training, and self-care techniques
- Training in problem-solving and cognitive-based coping strategies that increase perceived sense of control and address caregiving burden distress
- Interventions for depressive symptoms

Reference: Chung, M. L., Pressler, S. J., Dunbar, S. B., Lennie, T. A., & Moser, D. K. (2010). Predictors of depressive symptoms in caregivers of patients with heart failure. *Journal of Cardiovascular Nursing*, 25(5), 411–419.

* BOX 29-4 FOCUS ON OLDER ADULTS

- Older adults are incorrectly presumed to be more vulnerable to the psychosocial effect of stressors (Kasl, 1992). However, the diurnal pattern of HPA axis activity does change with age with higher evening levels of cortisol (Magri et al., 2006). As a result, sleep patterns may be altered, memory may be impaired (Lupien et al., 2005), and immune system functioning may be blunted (Graham et al., 2006). These changes can lead to increasing physical and mental frailty (Butcher & Lord, 2004).
- A study of stress and coping in patients aged 75 to 91 years revealed that such patients, in comparison with patients of other ages, were less likely to view their lives as having problems, and they expended less effort in coping (Aldwin et al., 1996). This view may arise from multiple factors, including life experiences and perspectives of older adults that make most problems seem insignificant, having acquired appropriate stress management techniques and increased acceptance of daily hassles.
- The timing of stress-inducing events can significantly influence older adults' ability to cope. Many older adults experience several stressful events (e.g., loss of a spouse and new medical diagnosis) within a brief time frame, which may result in reduced coping ability.
- Older adults with strong spiritual beliefs effectively use religious coping in response to medical illness and disasters (Foster, 1997).
- Major depressive disorder and anxiety disorders are the most prevalent mental health disorders in later life (Chapman & Perry, 2008; Skultety & Rodriguez, 2008).

Sociocultural Factors. Low socioeconomic status is not necessarily associated with more stress than better financial status is. You must not make assumptions about the sources of stress for an individual or family. However, some circumstances create higher risk of experiencing serious stressors or trauma. For example, living under conditions of continuing violence, living in disintegrated neighbourhoods, and homelessness can be damaging, especially for young people (Pender et al., 2002).

A person's cultural background also greatly influences the perception of and reaction to stress (Aldwin, 2000). Cultural context must be integrated into any assessment. Differences are observed from culturally distinct groups within the general population, such as Aboriginal cultures, as well as from immigrant populations. It is important to recognize that Aboriginal culture is not singular. Indeed, potential stressors vary by geographic region (e.g., whether patients live in urban centres, rural areas, or remote parts of Canada); by historical events, such as residential schooling; and by the financial status of a specific Aboriginal group. Although stressors related to immigration have been well described, ongoing stressors also may influence the health of families for generations. Initial stressors can include career and financial issues related to underemployment, loss of extended family supports, language barriers, and unfamiliarity regarding accessing health services (Mollica et al., 2001; Shen & Takeuchi, 2001). Later stressors can be related to raising children in a dual context (between cultural norms of the country of origin and the current environment) (Beiser et al., 2010). An example of how cultural background may influence health is behavioural responses to pain (Box 29-5).

Maturational Factors. Stressors vary with life stage and are not necessarily related to negative events. Important individual and family developmental milestones can be anticipated with excitement but can nonetheless be stressful. Pre-adolescents may experience stress related to self-esteem issues, changes in family structure as a result of divorce or death of a parent, or hospitalizations. As adolescents search for their identity with peer groups and separate from their families, they may view these developmental tasks as stressors. In addition, they must make decisions about using mind-altering substances, peer pressure, sexuality, jobs, school, and career choices; the decision-making process may also be viewed as stressful. Stress for adults can arise from major changes in individual and family life circumstances (Aguilera, 1998). These changes include the many milestones of beginning a family and a career, losing parents, helping children leave home, and accepting physical aging. In old age, stressors include the loss of autonomy and mastery, as a result of general frailty or health problems that limit mobility, stamina, and strength, and the loss of spouse, close friends, and family that provided social support over the years (Box 29-4).

* BOX 29-5 CULTURAL ASPECTS OF CARE

Cultural context shapes the types of environmental stimuli that lead to activation of stress response systems. For example, diverse cultures address developmental transitions and life's turning points differently. How a person leaves the parental home, experiences health crises or chronic illness, cares for the family, or becomes disabled or dependent are all culturally bound. Furthermore, how a person appraises stress is also dependent on the person's culture. Coping strategies are also influenced by culture. According to Aldwin (1992), cultures vary in their emotion-focused and problem-focused coping strategies. According to some cultures, emotions should be controlled; according to others, they should be expressed. *Problem-focused coping* refers to controlling or managing stress. In addition, cultures provide different institutions for coping with stress. These include the legal system for conflict resolution, advice givers or support groups, and rituals.

Implications for Practice

- Realize that stressors and coping styles vary with different cultures.
- Use introspection to examine your own perceptions of stress and coping in a cultural context.
- Assess the influence of culture on a patient's appraisal of stress.
- Determine the available resources within a patient's culture that may facilitate coping.

Source: Aldwin, C. M. (2000). *Stress, coping and development: An integrative perspective* (pp. 30–22). New York: Guilford Press.

Critical Thinking

When caring for a patient who is experiencing stress, you integrate knowledge from nursing and other disciplines, previous experiences, and information gathered from patients to understand the particular stressor, its meaning for the patient and family, and current and past events that influence their responses to this stressor. You must know the neurophysiological changes that occur in response to overwhelming or chronic stress. You must also be able to determine the patient's perception of the situation and help the patient identify and use coping strategies that have helped in the past. If the patient's usual coping skills are unsuccessful or support systems are inadequate, you must implement crisis intervention counseling (see "Crisis Intervention").

You should be confident in the belief that you can help the patient manage the current situation effectively. Patients who are overwhelmed and perceive events as being beyond their capacity to cope rely on you as their guide to action. Through a nurse's expert advice and counsel, many patients gain confidence in their own ability to manage the consequences of the recent event. Standards of practice can help you make an accurate assessment of the level of a patient's stress, previously successful coping mechanisms, and available support systems before you intervene.

Nursing Process

❖ Assessment

When assessing a patient's stress level and coping resources, you must ask the patient to share personal and sensitive

Figure 29-3 Critical thinking model for stress and coping assessment.

information. Therefore, you must first establish a trusting nurse–patient relationship. By asking open-ended questions, listening carefully, observing the patient's nonverbal behaviour, and observing the patient's environment, you learn about the patient's stress. You use critical thinking skills to synthesize and analyze information (Figure 29-3). Often patients have difficulty expressing what is troubling them until they have the opportunity to talk with someone who has time to listen.

Subjective Findings

When assessing a patient's level of stress and coping resources, you arrange a nonthreatening physical environment, without a desk as a barrier, for the interaction (Varcarolis, 2002). You assume the same height as the patient, arranging the interview environment so that eye contact can be comfortably maintained or avoided. By placing chairs at a 90-degree angle or side by side, you can reduce the intensity of the interaction (Varcarolis, 2002). You use the interview to determine the patient's view of the stress, past successful coping resources, any possible maladaptive coping, and adherence to prescribed medical recommendations, such as medication or diet (Monat & Lazarus, 1991; Table 29-1). If the patient is using denial as a coping mechanism, you must be alert to whether he or she is overlooking necessary information. Other patients may state that they feel overwhelmed and unable to cope, but with help, they can reduce their multiple interacting stressors to manageable pieces. As in all patient interactions, you must respect the confidentiality and sensitivity of the information shared.

► TABLE 29-1 Focused Assessment Interview

Factors to Assess	Questions and Approaches	Physical Assessment Strategies
Perception of stressor	Ask the patient what is of most concern at this time. Ask the patient about problems sleeping, eating, working, and concentrating. Ask whether the patient has had accidents in the home, in the car, or on the job. Ask about previous stressors that are influencing current appraisals.	Observe nonverbal behaviour and expressions of feelings that indicate anxiety, fear, anger, irritability, or tension.
Available coping resources	Ask the patient about current friendships and contacts with family members. Ask what the patient has done in the past to cope with similar problems or stress. Ask how the patient spends leisure time. Ask the patient to describe any specific stress management techniques.	Observe whether the patient is alone or with others. Observe grooming and hygiene. Observe the patient's communication skills. Determine whether the patient is able to ask for help. Observe developmental level and sociocultural circumstances.
Maladaptive coping used	Assess current and past patterns of use of tobacco, prescription or over-the-counter drugs, and caffeine.	Observe for effects of heavy use of tobacco, alcohol, illegal drugs, and caffeine.
Adherence to healthy practices	Ask whether the patient visits a physician or nurse practitioner regularly for checkups. Ask about nutritional habits, exercise, use of seat belts, helmets (if applicable), and safer sexual practices.	Monitor pulse, blood pressure, weight. Observe nonverbal behaviour.

Figure 29-4 Sharing a joke or laughing with patients can reduce stress and support a therapeutic relationship.

safety alert Medical conditions such as sleep apnea and thyroid dysfunction that are common in older adults can initially cause symptoms that mimic stress-related symptoms. For this reason, a thorough physical assessment of an older adult who appears stressed or anxious is necessary to rule out potentially serious medical disorders. In addition, in older adults, signs of stress and crisis must be differentiated from emerging dementia and also from acute confusion, a condition that can be life-threatening.

Objective Findings

You obtain further findings about stress and coping by observing the patient's appearance and nonverbal behaviour during the interview, including grooming and hygiene, handshake and gait, body language, speech quality, eye contact, and attitude. Before or at the end of the interview, depending on the patient's anxiety level, you take basic vital signs to assess for physiological signs of stress, such as elevated blood pressure, heart rate, or respiratory rate (Figure 29-4).

Patient Expectations

It is crucial that you understand the meaning the patient attaches to the precipitating event and how stress responses are affecting the patient's life. You must allow the patient time to express priorities for coping. For example, if a woman has just been told that a breast mass was identified on a routine mammogram, you must discern what the patient wants and needs most from you. Some patients identify an immediate need for information about biopsy or mastectomy; others need guidance and support on how to share the news with family members. In some cases, when nothing can be done to change or improve the situation, allowing the patient to use denial as a short-term coping mechanism can be helpful. However, once you understand patient expectations, you must not exclude important aspects of care simply because a patient does not identify them as needs.

❖Nursing Diagnosis

You cluster data that indicate a potential or actual stressor and the patient's response. Keeping in mind previous knowledge and experiences with patients under stress, you then make individualized nursing diagnoses (Box 29-6).

Nursing diagnoses for people experiencing stress generally focus on coping. Major defining characteristics of *ineffective coping* include verbalization of both an inability to cope and an inability to ask for help. You identify defining characteristics by asking patients what currently concerns them most and allowing them sufficient time to answer. You observe for nonverbal signs of anxiety, fear, anger, irritability, and tension. Other defining characteristics include the presence of life stressors, an inability to meet role expectations and basic needs, alteration in societal participation, self-destructive behaviour, change in usual communication patterns, high rate of accidents, excessive food intake, drinking, smoking, and sleep disturbances. Stress can result in multiple nursing diagnoses, such as the following:

- *Anxiety*
- *Caregiver role strain*
- *Chronic pain*

BOX 29-6 NURSING DIAGNOSTIC PROCESS

Assessment Activities	Defining Characteristics	Nursing Diagnosis
Ask patient about change in sleeping patterns.	Sleep disturbance; difficulty falling asleep at night or staying asleep Nightmares or disturbing dreams Sighing	Anxiety
Ask patient to complete a sleep diary for two weeks.	Excessive sleeping	
Observe patient's behaviour and response to questions during assessment.	Fatigue Inability to concentrate Inaccurate response to questions Inappropriate laughing or crying	
Observe patient's appearance.	Poor grooming Self-harm	
Ask patient about changes in eating patterns.	Weight gain or loss Lack of interest in food	

- *Post-traumatic stress disorder*
- *Powerlessness*

Crises differ from stressors in the degree of severity, although stressors and crises have many similarities. A patient who perceives a situation as stressful, who is unable to cope in ways that have worked before, and who has insufficient support is experiencing a crisis. A crisis can be devastating and requires you to help mobilize all resources available (Aguilera, 1998).

❖Planning

Goals and Outcomes

Desirable outcomes for people experiencing stress are (1) effective coping, (2) coping by their family, (3) emotional health of the caregiver, and (4) psychosocial adjustment to life changes (Moorhead et al., 2008). You may select interventions for stress and improved coping such as coping enhancement or crisis intervention, which are in the *Nursing Interventions Classification (NIC)* (Dochterman et al., 2008). In addition, you select individualized interventions after you consider the nursing diagnosis, the resources available to the patient, and the goals identified by the patient and nurse (Figure 29-5).

Nursing interventions may be designed within the framework of primary, secondary, and tertiary prevention. At the primary level of prevention, individuals and populations who may be at risk for stress are identified (Stuart & Wright, 1995). At the secondary level, nursing actions are directed at symptoms, such as decreasing the frequency or intensity of specific symptoms. At the tertiary level, nursing interventions assist the patient in readapting and might include relaxation training and time management training (Box 29-7). Another method of planning care involves using a concept map (Figure 29-6). You

Figure 29-5 Critical thinking model for stress and coping planning.

create the map after identifying relevant nursing diagnoses from the assessment database. In this example, the nursing diagnoses are linked to the patient's medical diagnosis of PTSD. The concept map shows the relationships with the nursing diagnoses: PTSD, *ineffective coping*, *anxiety*, and *risk for other-directed violence*. In this approach, you use critical thinking skills to organize patient data and plan for patient-centred care.

Just as the nursing assessment of stress and coping depends on patient perception of the problem and coping resources, interventions focus on a partnership of the nurse with the patient and support system, usually the family. In the case of a family or community stressor and impaired family or community coping, the view of the situation and resources is broader.

Setting Priorities

When you prioritize needs for a person experiencing stress or a crisis, the first question to be answered is "What is happening in your life that you needed to come today?" or "What happened in your life that is *different*?" This question requires the patient to focus. You should then assess the patient's perception of the event, situational supports, and what the patient usually does when faced with a problem (Aguilera, 1998). As in all areas of nursing, safety of the patient and family is the first priority.

► BOX 29-7 NURSING CARE PLAN

Caregiver Role Strain

Assessment

When the professional nurse first goes to Carl's house, she finds the home to be in slight disarray. The lawn is overgrown, dirty dishes are in the sink, and an empty can of soup is sitting on the kitchen counter. Carl is standing in the living room, folding clothes from a laundry basket, and Evelyn, Carl's wife, is sitting in a chair watching TV. Evelyn recently received a diagnosis of Alzheimer's disease.

Assessment Activities

Ask Carl about his recent stressors and coping strategies.

Findings and Defining Characteristics

He continues to fold clothes during the visit, stating, "There's so much to do that I don't even know where to begin." Carl describes being awakened three to four times per night to find Evelyn wandering in the house.

He states that he has no outside activities and his children live in other provinces.

He does have several close friends who live nearby, but he does not know of community resources.

Observe Carl's grooming and hygiene.

Carl is unshaven and appears dishevelled.

Ask Carl about his sleep and nutrition patterns.

Carl states that he has lost 9 kg in the past 6 months and that his appetite has been poor.

Assess Carl's mood and affect by asking how he is feeling.

Carl states, "I feel very tired. Everything feels overwhelming."

Assess Carl's suicide potential.

Carl denies being suicidal.

Assess health status and health care status.

Carl has not seen a nurse practitioner or physician for his own health in over a year.

Nursing Diagnosis: Caregiver role strain related to recent diagnosis of wife's Alzheimer's disease

Planning

Goal (Nursing Outcomes Classification)*

Patient will appear rested in 1 month.

Expected Outcomes

Caregiver's Physical Health

Patient will report waking up less frequently during the night within 1 week.
Patient will verbalize approaches used to involve other people in caregiving activities within 2 weeks.

Patient will maintain a stable weight over next 4 weeks.

Patient will re-establish normal eating pattern within 1 week.
Patient will report improved appetite.

Patient will state that he has resumed one outside activity within 1 month.

Caregiver's Lifestyle Disruption

Patient will report within 1 week a balanced routine that incorporates time for own rest or relaxation.

*Outcome classification labels from Moorhead, S., Johnson, M., & Maas, M. L. (Eds.). (2008). *Nursing outcomes classification (NOC)* (4th ed.). St Louis, MO: Mosby.

Interventions (Nursing Interventions Classification)[†]

Caregiver Support

Assist patient in establishing a consistent care routine.

Rationale

Routines can help tasks be simplified and more time efficient.

Discuss ways that patient agrees will simplify care routine, such as hiring a teenage neighbour to mow the lawn, buying frozen meals, having groceries delivered, and having a cleaning service twice a month.

Caregivers experience stress outside of their caregiving roles. Frequently, providing ways to assist the caregiver with home maintenance, meal planning, and shopping assists caregivers with stress management.

Identify sources of respite care by encouraging patient to identify available friends who can assist with caregiving.

Caregiving cannot normally be successful if it involves only one caregiver. Caregiver may be hesitant to ask for help because of past family conflict (Etters et al., 2008).

Explore community resources such as home care, adult day care, and Meals on Wheels with patient.

Feelings of burden have been found to be lower among caregivers with social supports (Solomon & Draine, 1995).

Teach patient stress-management techniques.

Stress, especially long-term stress, can precipitate physical illness.

BOX 29-7 NURSING CARE PLAN—cont'd

Interventions (Nursing Interventions Classification)[†]

Caregiver Support

Set up monthly health checks for patient that include vital sign and weight measurements.

Teaching the caregiver health maintenance strategies is important for sustaining his own physical and mental health (Dochterman & Bulechek, 2004).

[†]Intervention classification labels from Dochterman, J. M., Bulechek, G. M., & Butcher, H.K. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St Louis, MO: Mosby.

Evaluation

Nursing Actions

Observe for signs of fatigue.

Patient Response and Finding

Carl states he feels more rested and less depressed.

Achievement of Outcome

Carl is able to sleep for 6 hours during night and takes a 30-minute nap in the afternoon.

Review new care routines. Ask patient what other modifications may need to be made.

Carl buys frozen meals to use when he is busy with other caregiving responsibilities.

Carl has reduced his personal expectation that he must cook every meal himself.

Ask patient about how community and additional family support is helping to relieve stress.

Meals on Wheels delivers lunch 5 days per week. A neighbour mows the lawn for Carl.

Carl is mobilizing community resources.

Ask patient to compare past and current energy levels.

Carl reports having more energy and smiles spontaneously.

Carl has improved balance between Evelyn's and his own routines.

Weigh patient regularly.

Carl reports gaining 2 kg in 1 month.

Carl has resumed a normal eating pattern.

Ask patient about recent food intake.

Carl reports having eaten lunch with Evelyn on the day of the visit.

Carl has been able to sustain reasonable food intake recently.

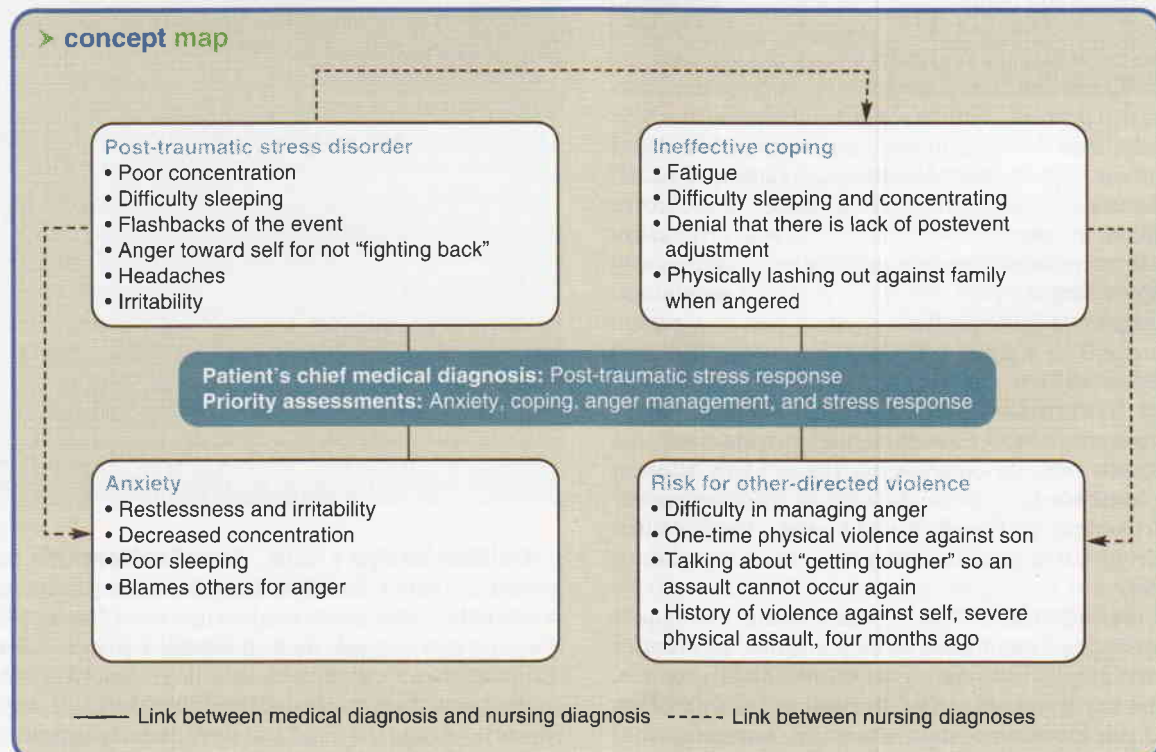

Figure 29-6 Concept map for patient with PTSD after experiencing a severe physical assault four months ago.

safety alert Direct questions help to determine whether the person is suicidal or homicidal. You might ask, "Have you thought that life is not worth living? Are those thoughts with you most of the day?" "Have you thought your problems would be solved if that other person were not around anymore?" If so, you should calmly determine whether the patient has a plan and determine how lethal the means are. If suicide or homicide is not an issue, you should consider other threats to the safety of people who are under the patient's care and provide for their temporary care or supervision if necessary. When immediate assessment is completed and safety is ensured, the problem-solving process should begin (Aguilera, 1998).

Continuity of Care

Sometimes the scope of nursing practice is insufficient to meet all of the patient's needs. For patients experiencing stress from medical conditions or psychiatric disorders, you must consult with advanced practice mental health nurses, psychiatrists, psychologists, psychiatric social workers, or other mental health experts. Such a multidisciplinary approach to care is often most effective in addressing the holistic needs of the patient and should be included in the planning of care. Your role is to recognize the need for collaboration and consultation, inform the patient about potential resources, and make arrangements for interventions, such as consultations, group sessions, or therapy as needed.

Implementation

Health Promotion

Three primary modes of intervention for stress are to decrease stress-producing situations, increase resistance to stress, and learn skills that reduce physiological and psychological responses to stress (Pender et al., 2002). You are in a position to educate patients and families about the importance of health promotion (Boxes 29-8 and 29-9). Several strategies help increase resistance to stress and reduce response to stress.

Regular Exercise. A regular exercise program improves muscle tone and posture, controls weight, reduces tension, and promotes relaxation. In addition, exercise improves mood and immune and cardiopulmonary functioning (Hume et al., 2011; Walsh et al., 2011). Patients who have a history of a chronic illness, who are at risk for developing an illness, or who are older than 35 years should begin a physical exercise program only after discussing the plan with a physician. In general, for a fitness program to have positive physical effects, a person should exercise 3 to 4 times per week for at least 20 to 30 minutes (Figure 29-7).

Support Systems. A support system of family, friends, and colleagues who listen, offer advice, and provide emotional support benefits patients experiencing stress. Many support groups are available to individuals, such as those sponsored by the Heart and Stroke Foundation of Canada, the Canadian Cancer Society, local hospitals and churches, and mental health organizations.

Time Management. Time management techniques include developing lists of tasks to be performed in order of priority: for example, tasks that require immediate attention, those that are important but can be delayed, and those that are routine and can be accomplished when time becomes available. In many cases, setting priorities helps individuals identify tasks that are not necessary or perhaps can even be delegated to someone else.

* BOX 29-8

FOCUS ON PRIMARY HEALTH CARE

Nurses address their patient's stress or potential stress in many different primary health care settings. In a community setting, you might instruct a group of teenage mothers on how to care for their newborns and themselves. The goal of the instruction is to improve the health and safety of the babies and to prevent stress, health breakdown, and crises in the lives of vulnerable mothers. In a home setting, you might help the family of a patient who has cancer to recognize and deal with symptoms of stress in their lives. In an interview at a community clinic, you might assess the stress in the life of a patient with sleep problems and plan interventions to help the patient sleep. Nurse practitioners who work in primary health care settings can provide a range of services related to family health and ongoing management of chronic health problems.

* BOX 29-9

PATIENT TEACHING

Stress Management Strategies

Objective

- Improved coping with daily hassles in the workplace (such as depending on others for transportation to work, chronically late co-worker, multiple competing work demands, intense work demands at specific times)

Teaching Strategies

- Teach the patient how to break down hassles into specific aspects in order to begin coping with them.
- Instruct the patient to avoid impulsive changes in lifestyle when stressed.
- Instruct the patient in time management skills to become more organized and set priorities.
- Assist the patient in examining lifestyle issues that may serve as stress relievers, such as walking during the lunch hour and other recreational activities.
- Assist the patient in examining dietary sources of increased tension, such as excessive caffeine intake (e.g., coffee, tea, chocolate).
- Assist the patient in building a network of social support.
- Train the patient in progressive muscle relaxation or other relaxation techniques.

Evaluation

- Observe the patient for signs of active coping strategies.
- Ask the patient to keep a record of hours of sleep.
- Ask the patient to list activities that are soothing or enjoyable.

Data from Pender, N. J., Murdaugh, C., & Parsons, M. A. (2002). *Health promotion in nursing practice* (4th ed.). Upper Saddle River, NJ: Haworth Press.

Guided Imagery and Visualization. The concept of guided imagery is based on the belief that a person can significantly reduce stress with imagination (see Chapter 34). Guided imagery is a relaxed state in which a person actively uses imagination to visualize a soothing, peaceful setting. The image created or suggested typically evokes many sensory words to engage the mind and offer distraction and relaxation.

Progressive Muscle Relaxation. In the presence of anxiety-provoking thoughts and events, a common physiological symptom is muscle tension. Physiological tension is

Figure 29-7 Regular exercise assists in coping with stress.

diminished through a systematic approach to releasing tension in major muscle groups. A relaxed state is achieved typically through deep chest breathing, and then the patient is directed to alternately tighten and relax muscles in specific groupings (see Chapter 34).

Assertiveness Training. Assertiveness comprises skills that help individuals communicate their needs and desires effectively. The ability to resolve conflict through assertiveness training is important for reducing stress. When assertiveness is taught in a group setting, benefits of the experience are increased.

Journal Writing. For many people, keeping a private, personal journal provides a therapeutic outlet for stress, and it is well within the realm of nursing to suggest journal keeping to patients experiencing difficult situations. In a private journal, patients can express a full range of emotion and vent their feelings honestly without hurting anyone's feelings and without concern for how they might appear to others. The writings can help individuals become more self-reflective, to increase their awareness of sources of stress, and to see how effective their coping strategies have been. Journal entries can also be shared with health care providers to help plan targeted interventions.

Stress Management in Your Workplace. Rapid changes in health care technology, diversity in the workforce, organizational restructuring, and changing work systems can place stress on nurses (Bauman et al., 2001; Manning et al., 1999). Additional causes of job stress include particular job assignments (Box 29-10), difficult schedules that include more than two different work shifts in short periods of time, working predominantly night shifts, fear of failure, and inadequate support services (Manning et al., 1999). **Burnout** occurs as a result of chronic stress. Burnout is "a syndrome of emotional

BOX 29-10 NURSING STORY

Missing What Is Important

I was so keen! I wanted to be such a good nurse. Thus, in the second year of my nursing program, I began my first day on an assessment unit within our provincial psychiatric hospital with eager anticipation of testing my newly learned communication techniques, mixed with some curiosity and admitted anxiety about how I would react to patients. As it turned out, what I was stressed about was so far off the mark! I was so concerned about how I would react to patients that I did not consider how patients would react to me! We were to complete verbatim reports regarding our interactions with our patients. However, my assigned patient was a middle-aged man with paranoid schizophrenia who apparently was suspicious of new people. It was suggested that I "hang around" the unit for a few days, so that my patient could get used to seeing me before I actually approached him. But what about those verbatim reports? How could I initiate the first conversation? Maybe discreet observations could fill in for the time being. I was caught up in my role as an unobtrusive staff member. On the second day, the patient abruptly approached me and in an angry tone stated, "You have been following me and watching me for two days!" So much for my discretion. In focusing only on my perceptions and needs, I had thought little about how perception, like communication, can be different for the participants. My spontaneous response was "You're right, I have. I just didn't know how to approach you." His anger dissolved into a laugh at my awkwardness. That clear, honest response was the start of a very rewarding nurse-patient relationship that spanned the entire two-month rotation. He taught me so much about mental health nursing: how perceptions about potential stressors affected our interactions, how spontaneity could be powerful in interactions, and how my self-perceptions needed to be checked against the perceptions of my patients, regardless of diagnosis. I subsequently enjoyed mental health as a career choice, which spanned more than 30 years. I worked with many different clinical populations over the years, but I still remember my stress and distress over my first patient and how it made me blind to what was really going on.

exhaustion, depersonalization of others, and perceptions of reduced personal accomplishment, resulting from intense involvement with people in a caregiving environment" (Cuneo et al., 2011; Gibbons 2010). This can be reflected in high rates of sick leave, irritability with co-workers, increased risk of errors at work, and increased home stress. Nurses are not immune to maladaptive coping, such as use of alcohol, in response to chronic stress or burnout.

Primary prevention is essential to addressing risk for burnout and is important for all health providers. Personal stress management strategies need to be a part of professional practice; they can include working on crafts, scheduled social outings with friends, participation in a team sport or an individual recreational or physical activity, limiting amount of overtime worked, taking an art class, or simply reading for pleasure. If nurses recognize feelings of burnout, they can engage in some of the same strategies that help patients: increase their own self-reflections regarding potential sources of stress, use daily journal writing to increase recognition of contextual factors, seek a colleague or mentor to help with their reflections, create an inventory of available personal and support resources, and devise a plan for addressing the various stressors in a manageable and positive manner. An important step is identifying the limits and scope of responsibilities at

work (Cuneo et al., 2011; Gibbons 2010). It is essential that you recognize the areas over which you have control and can change and those for which you do not have responsibility.

Acute Care

Crisis Intervention. When stress overwhelms a person's usual coping mechanisms and all available resources must be mobilized, the situation becomes a crisis. A crisis creates a turning point in a person's life because it changes the direction of a person's life in some way. According to Aguilera (1998), the precipitating event usually occurs one to two weeks before the individual seeks help, but it may have occurred within the past 24 hours. In general, a crisis is resolved in some way within approximately six weeks. The aim of crisis intervention is to return the person to a precrisis level of functioning and to promote growth (Figure 29-8). The use of unfamiliar strategies can result either in a heightened awareness of previously unrecognized strengths and resources or in deterioration in functioning. Thus, a crisis is often referred to as a situation of both danger and opportunity. Some people or families

emerge from a crisis state functioning more effectively, whereas others are weakened, and still others are rendered completely dysfunctional.

Crisis intervention is a specific type of brief psychotherapy with prescribed steps (Rose et al., 2003). Crisis intervention is more directive than traditional psychotherapy or counselling and can be used by any member of the health care team who has been trained in its techniques. The basic approach is problem solving, and the focus is on only the problem presented by the crisis.

When using a crisis intervention approach, you help the patient make the mental connection between the stressful event and the patient's reaction to it. This is crucial because the patient may be unable to envision the whole situation clearly. You also help the patient become aware of current feelings, such as anger, grief, or guilt, in order to reduce tension. In addition, you help the patient explore coping mechanisms, perhaps identifying ways of coping that the patient had not thought of. Finally, you may help increase the patient's social contacts if the patient has been internally focused and isolated.

Figure 29-8 Crisis intervention model. **Source:** Redrawn from Aguilera, D. C. (1998). *Crisis intervention: Theory and methodology* (8th ed.). St Louis, MO: Mosby.

Restorative and Continuing Care

A person under stress recovers when the stress is removed or coping strategies are successful; however, a person who has experienced a crisis has changed, and the effects may last for years or for the rest of the person's life (Walsh et al., 2011). The final stage of adapting to a crisis is acknowledgement of the long-term implications of the crisis.

❖ Evaluation

Patient Care

By evaluating the goals and expected outcomes of care, you know whether the nursing interventions were effective and whether the patient is coping with the identified stress. You review the measurable goals and assess whether the patient has met the criteria for success as stated in the outcomes. If the nursing interventions have not been effective in helping the patient achieve targeted goals, you must re-evaluate the strategies implemented and revise the care plan in light of the patient's current health status (Figure 29-9).

To evaluate whether goals and outcomes of care have been achieved, you observe patient behaviours and interactions between the patient and family, if appropriate. If your contact with a patient ends before goals have been achieved, the patient should be referred to appropriate resources so that progress is not delayed or interrupted.

Figure 29-9 Critical thinking model for stress and coping evaluation.

Patient Expectations

It is crucial to maintain ongoing communication with patients in regard to the care plan. Patients under severe stress or trauma often feel powerless and vulnerable. You can help reduce these feelings by actively involving patients and families in assessment, prioritizing, goal setting, and evaluation. Being involved enables patients to direct their energy positively and encourages them to take responsibility for their health. It also facilitates open communication, which makes it easier for the patient to report on interventions that are successful and helps you better understand why some interventions fail to meet their goals.

❖ KEY CONCEPTS

- Physiological and psychological frameworks have been developed to describe how stress affects biological systems and psychological well-being.
- Overwhelming or chronic stress can increase the risks of (1) serious and long-standing physical and mental health problems; (2) choosing coping strategies that are unhealthy, such as isolating oneself, not getting enough rest or a proper diet, or using tobacco, alcohol, or caffeine; (3) ignoring warning signs of illness; and (4) neglecting to take prescribed medicines or treatments.
- A person is under psychological stress only if the person evaluates the event or circumstance as personally significant. Such an evaluation of an event for its personal meaning is called *primary appraisal*.
- Several types of stressors are work stressors, family stressors, chronic stressors, acute stressors, daily hassles, traumatic events, and crisis.
- Rapid changes in health care technology, diversity in the workforce, organizational redesign, and changing work systems can place nurses at risk for stress-related symptoms and burnout.
- Potential stressors and coping mechanisms vary across the lifespan: from childhood through adolescence, adulthood, and old age.
- Coping is a means of managing psychological stress and reflects a dynamic process in response to the current situation, past experiences, and available resources.
- Three primary modes for stress intervention are to decrease stress-producing situations, increase resistance to stress, and learn skills that reduce physiological response to stress.
- If stress is so severe that the patient is unable to cope in any ways that have worked before, the patient is experiencing a crisis.
- A crisis is a turning point in life and can be developmental or situational.
- In general, a crisis is resolved in some way within approximately six weeks. Crisis intervention aims to return the person to a pre-crisis level of functioning and to promote growth.

❖ CRITICAL THINKING EXERCISES

1. You are caring for a 30-year-old woman who has recently had surgery as a first step in her treatment for metastatic breast cancer. She is the lone parent and sole provider for three young children (all younger than seven years). Discuss the various stressors that must be considered when you write an appropriate discharge plan.
2. A patient comes to the emergency department with a complaint of dizziness, which is not related to any physical finding on examination. During the health history, the patient reports

that her life is very stressful and she is barely coping. She finalized her divorce three months ago, is working 32 hours per week, and is attending college. Her ex-husband recently lost his job and can no longer pay child support. She tearfully confesses that she thinks she might be pregnant but does not want her ex-husband to know. Develop nursing diagnoses related to this situation.

3. An older woman is admitted to the hospital with a fractured hip. Before her injury, she lived with her husband, who has advancing Alzheimer's disease. While she is hospitalized, he is staying with a niece who lives 50 km away, but this cannot be a permanent situation because her niece is also in frail health. The patient has no children who can help her when she returns home. She is concerned not only about who will care for her after she is discharged but also about her husband's care. What approach would be the best to take in establishing goals for treatment?

✦ REVIEW QUESTIONS

1. The vital functions necessary for survival, which include heart rate, blood pressure, and respiration, are controlled by the
 1. Medulla oblongata
 2. Reticular formation
 3. Pituitary gland
 4. Limbic system
2. While assessing a person for effects of the general adaptation syndrome, you should be aware that
 1. Heart rate increases in the adaptation state
 2. Blood volume increases in the exhaustion stage
 3. Vital signs return to normal in the exhaustion stage
 4. Blood glucose level increases during the alarm reaction stage
3. When performing an assessment of a young woman who was in an automobile accident six months before, you learn that the woman has vivid images of the crash whenever she hears a loud, sudden noise. You recognize that these reactions are flashbacks, which are symptoms of
 1. Social phobia
 2. Acute anxiety
 3. Post-traumatic stress disorder
 4. Borderline personality disorder
4. A man is adjusting to a chronic illness; the chronic illness can be considered
 1. A sociocultural stressor
 2. A maturational stressor
 3. A situational stressor
 4. An environmental stressor
5. A child who has been in a house fire comes to the emergency department with her parents. The child and parents are upset and tearful. During your first assessment for stress, what should you say?
 1. "Tell me whom I can call to help you."
 2. "Tell me what upsets you the most about this experience."
 3. "I will contact someone who can help get you temporary housing."
 4. "I will sit with you until other family members can come help you get settled."
6. You are evaluating the coping strategies of a patient experiencing stress from receiving a new diagnosis of multiple sclerosis and psychomotor impairment. You realized that the patient is coping successfully when the patient makes which of the following statements?
 1. "I am going to learn to drive a car so I can be more independent."
 2. "My sister says she feels better when she goes shopping, so I will go shopping."
 3. "I have always felt better when I go for a long walk. I will do that when I get home."
 4. "I am going to attend a support group to learn more about multiple sclerosis and what I will be able to do."
7. You know that the patient is recovering from the stress of an emergency surgery when the patient makes which of the following statements?
 1. "I am going to change jobs."
 2. "I am learning progressive relaxation training."
 3. "I plan to have plastic surgery while I am here in the hospital."
 4. "I am planning to sell my house and move within the next six weeks."
8. A staff nurse is talking with her nursing supervisor about the stress she feels from having transferred to a new inpatient unit. The supervising nurse recognizes that
 1. Nurses who feel stress usually pass the stress along to their patients
 2. A nurse who feels stress is ineffective as a nurse and should not be working
 3. Nurses who talk about feeling stress are unprofessional and should calm down
 4. Nurses frequently experience stress with the rapid changes in health care technology and organizational restructuring
9. In general, a person's crisis is resolved in some way within approximately
 1. six weeks
 2. one month
 3. six months
 4. two weeks

Vital Signs

Written by Shelley Jeske, RN, MN

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Explain the principles and mechanisms of thermoregulation.
- Describe nursing measures that promote heat loss and heat conservation.
- Discuss physiological changes associated with fever.
- Accurately assess temperature via multiple routes: tympanic, oral, temporal, rectal, and axillary.
- Accurately assess pulse, respirations, oxygen saturation, and blood pressure.
- Explain the physiology of normal regulation of blood pressure, pulse, oxygen saturation, and respirations.
- Describe factors that cause variations in body temperature, pulse, oxygen saturation, respirations, and blood pressure.
- Describe ethnic variations in blood pressure.
- Identify ranges of acceptable vital sign values for an infant, a child, and an adult.
- Explain variations in technique used to assess an infant's, a child's, and an adult's vital signs.
- Describe the benefits and precautions involving self-measurement of blood pressure.
- Identify when vital signs should be measured.
- Accurately record and report vital sign measurements.
- Appropriately delegate vital sign measurement to unregulated care providers.

The most frequent measurements obtained by health care providers are those of temperature, pulse, blood pressure, respiratory rate, and oxygen saturation. These measurements indicate the effectiveness of circulatory, respiratory, neural, and endocrine body functions. Because of their importance, they are referred to as **vital signs (VS)**. Many factors such as pain, environmental temperature, physical state, activities, or illness can cause vital signs to change, sometimes to values outside an acceptable range. Recently, pain has been referred to as the "fifth vital sign," demonstrating the importance of

its assessment not only as a factor that influences the standard vital signs, but as an indicator of the necessity to ensure the inclusion of its assessment as part of baseline data. A detailed pain assessment is addressed in Chapter 41.

Vital signs provide important data to determine the usual state of health (baseline data). A change in vital signs indicates a change in physiological function, which may signal the need for medical or nursing intervention. Measuring vital signs is a quick and efficient way of monitoring a patient's condition, identifying problems, or evaluating responses to interventions. With knowledge of the physiological variables influencing vital signs and recognition of the relationship of vital signs changes to other physical assessment findings, precise determinations of health are made. Inspection, palpation, and auscultation are used to determine vital signs. These simple skills should not be taken for granted. Careful measurement techniques ensure accurate and consistent findings. Vital signs and other physiological measurements are the basis for clinical problem solving.

Guidelines for Measuring Vital Signs

Vital signs are an important part of all assessments. Data are obtained during a complete physical assessment (see Chapter 31) and as needed to assess a patient's condition. Vital sign measurements during a routine physical examination provide a baseline for future assessments. The patient's needs and condition determine when, where, how, and by whom vital signs are measured. The nurse must measure vital signs correctly or delegate their measurement appropriately. Values must be understood and interpreted, findings communicated appropriately, and interventions begun as needed. Box 30-1 lists acceptable adult values.

Use the following guidelines to incorporate vital sign measurement into your nursing practice:

- Unregulated care providers may measure selected vital signs (i.e., in stable patients), and then the nurse responsible for the patient may interpret and act upon these measurements.
- Use equipment that is functional and appropriate for the size and age of the patient to ensure accurate findings (e.g., an oral thermometer is not appropriate for use in an infant).

- Select equipment on the basis of the patient's condition and characteristics (e.g., an adult-size blood pressure cuff should not be used for a child).
- Minimize environmental factors that may affect vital signs (e.g., assessing the patient's temperature in a warm, humid room may yield a value that is not a true indicator of the patient's condition).
- Use an organized, step-by-step approach to ensure accuracy.
- Approach the patient in a calm, caring manner while demonstrating proficiency in handling supplies needed for vital sign measurement. The manner of approach can alter vital signs.
- Follow guidelines cited in Box 30-2 to decide frequency of vital sign assessment. Increase the frequency of vital sign assessment if the patient's condition warrants it (i.e., frequency of vital signs ordered by the prescribing health care provider is the *minimum* number of times that they should be checked).
- Use vital sign measurements to determine indications for prescribed medication administration (e.g., certain cardiac medications are given only if pulse or blood pressure values are in a certain range; antipyretics are administered only when temperature is elevated outside the acceptable range for the patient).
- Analyze the results of vital sign measurement by considering the patient's usual values, medical history, therapies, and prescribed medications. A patient's usual values may differ from the acceptable range for that age or physical state. Some illnesses or treatments cause predictable changes in vital signs. Some medications affect one or more vital signs. The nurse is often in the best position to assess all clinical findings about a patient and must be knowledgeable of related physical signs or symptoms and the patient's ongoing health status.
- Baseline measurements allow the identification of changes in vital signs. When vital signs appear abnormal, it is useful to have another nurse repeat the measurement. Verify, document, and communicate significant changes in vital signs to the prescribing health care provider or nurse in charge.
- Involve the patient and/or caregiver in vital sign assessment and the significance of findings through implementation of teaching plans as necessary.

► BOX 30-1

Vital Signs: Acceptable Readings for Adults

Temperature Range: 36°C to 38°C (Hooper et al., 2009)

Average oral/tympanic/temporal: 37°C

Average rectal: 37.5°C

Average axillary: 36.5°C

Pulse

60–100 beats per minute

Respirations

12–20 breaths per minute

Blood Pressure

Systolic: 120–139 mm Hg

Diastolic: 80–89 mm Hg

Pulse pressure: 30–50 mm Hg

► BOX 30-2

When to Measure Vital Signs

Upon admission to a health care facility

During a home care visit

According to the prescribing health care provider's order or the health facility's standards of practice

Before, during, and after a surgical procedure or an invasive diagnostic procedure

Before, during, and after the administration of blood products

Before, during, and after administration of medications that affect cardiovascular, respiratory, and temperature-control function

When patient's general physical condition changes (e.g., loss of consciousness or increased pain)

Before and after nursing interventions that affect a vital sign (e.g., before a patient previously on bed rest ambulates or before a patient performs range-of-motion exercises)

When a patient reports nonspecific symptoms of physical distress (e.g., feeling "funny" or "different")

Figure 30-1 Ranges of normal temperature values and physiological consequences of abnormal body temperature.

Body Temperature

Physiology

Body temperature is the difference between the amount of heat produced by body processes and the amount lost to the external environment. Despite extremes in environmental conditions and physical activity, temperature-control mechanisms keep the body's **core temperature** (temperature of structures deep within the body) relatively constant (Figure 30-1) whereas body surface temperature fluctuates, depending on blood flow to the skin and the amount of heat lost to the external environment. Because of these surface temperature fluctuations, acceptable body temperature ranges from 36°C to 38°C, a narrow range in which the body's tissues and cells function best.

The measurement of body temperature is aimed at obtaining an average temperature of core body tissues. Sites reflecting core temperatures are more reliable indicators of body temperature than are sites reflecting surface temperatures (Box 30-3). The temperature value obtained may also differ between one measurement site and another. In clinical practice, nurses learn the temperature range of individual patients, recognizing that no single temperature reading is normal for all people.

Regulation. The balance between heat lost and heat produced, or **thermoregulation**, is precisely regulated by physiological and behavioural mechanisms. For body temperature to stay constant and within an acceptable range, the relationship between heat production and heat loss must be closely maintained. This relationship is regulated by neurological and cardiovascular mechanisms. To regulate patients' temperatures, knowledge of temperature-control mechanisms is applied.

Neural and Vascular Control. The **hypothalamus**, located between the cerebral hemispheres, controls body temperature the same way that a thermostat works in a building. A comfortable temperature is the *set point* at which a heating system operates. In the building, a decrease in environmental temperature activates the furnace, whereas a rise in temperature shuts the system down. The hypothalamus is like the building's furnace; it senses minor changes in body temperature. The anterior hypothalamus controls heat loss, and the posterior hypothalamus controls heat production.

When nerve cells in the anterior hypothalamus become heated above the set point, impulses are sent to reduce body temperature. Mechanisms of heat loss include sweating, vasodilation (widening) of blood vessels, and inhibition of heat production. Blood is redistributed to surface vessels to promote heat loss. If the posterior hypothalamus senses that the body's temperature is lower than the set point, heat conservation mechanisms are instituted: vasoconstriction (narrowing) of blood vessels reduces blood flow to the skin and extremities. Compensatory heat is produced through voluntary muscle contraction and muscle shivering. When vasoconstriction is ineffective in preventing additional heat loss, shivering begins. Disease or trauma to the hypothalamus or to the spinal cord, which carries hypothalamic messages, can cause serious alterations in temperature control.

Heat Production. Thermoregulation depends on the normal function of heat production processes. Heat is produced in the body as a by-product of metabolism, the chemical reaction in all body cells. Food is the primary fuel source for metabolism. Activities requiring additional chemical reactions increase metabolic rate. As metabolism increases, additional heat is produced. When metabolism decreases, less heat is produced. Heat production occurs during rest, voluntary movements, involuntary shivering, and nonshivering thermogenesis.

Basal metabolism accounts for the heat produced by the body at absolute rest. The average **basal metabolic rate (BMR)** depends on the body surface area. Thyroid hormones also affect the BMR. By promoting the breakdown of body glucose and fat, thyroid hormones increase the rate of chemical reactions in almost all cells of the body. When large amounts of thyroid hormones are secreted, the BMR can increase 100% above normal. Absence of thyroid hormones can reduce the BMR by half, causing a decrease in heat production. The male sex hormone testosterone increases BMR. Men have a higher BMR than do women. Voluntary movements such as muscular activity during exercise require additional energy. Metabolic rates can increase up to 2000 times normal during exercise. Heat production can increase up to 50 times normal.

Shivering is an involuntary body response to temperature differences in the body. The skeletal muscle movement during shivering requires significant energy. In vulnerable patients, shivering can seriously deplete energy sources, which results in further physiological deterioration. Shivering can increase heat production four to five times greater than normal. The heat produced assists in equalizing body temperature, and shivering ceases.

Nonshivering thermogenesis occurs primarily in newborns and is the main source of heat generation. Until approximately two weeks of age, newborns cannot shiver, thereby relying on vasoconstriction through an increase in norepinephrine (Soll, 2008). In addition, a limited amount of vascular brown tissue (fat) is metabolized for heat production.

Heat Loss. Heat loss and heat production occur simultaneously. The skin's structure and exposure to the environment result in constant, normal heat loss through radiation, conduction, convection, and evaporation.

Radiation is the transfer of heat from the surface of one object to the surface of another without direct contact between the two. Up to 85% of the human body's surface area radiates heat to the environment. Peripheral vasodilation increases blood flow from internal organs to the skin to increase radiant heat loss. Peripheral vasoconstriction minimizes radiant heat loss. Radiation increases as the temperature difference between the objects increases. If the environment is warmer than the skin, the body absorbs heat through radiation.

Heat loss is increased through radiation by removing clothing or blankets. The patient's position enhances radiation heat loss (e.g., standing exposes a greater radiating surface area, and lying in a fetal position minimizes heat radiation). Covering the body with dark, closely woven clothing also reduces the amount of heat lost from radiation.

Conduction is the transfer of heat from one object to another through direct contact. Heat is conducted through contact with solids, liquids, and gases. When warm skin touches a cooler object, heat is lost. Conduction normally accounts for a small amount of heat loss. Interventions such as applying a cool cloth increase conductive heat loss. Applying several layers of clothing reduces conductive loss. The body gains heat by conduction when contact is made with materials warmer than skin temperature (e.g., application of an aquathermia pad).

Convection is the transfer of heat away from the body by air movement. A fan promotes heat loss through convection. Convective heat loss increases when moistened skin comes into contact with slightly moving air.

Evaporation is the transfer of heat energy when a liquid is changed to a gas. The body continuously loses heat by evaporation. About 600 to 900 mL per day evaporates from the skin and lungs, resulting in water and heat loss. By regulating perspiration (sweating), the body promotes additional evaporative heat loss. Millions of sweat glands located in the dermis of the skin secrete sweat through tiny ducts on the skin's surface. When body temperature rises, the anterior hypothalamus signals the sweat glands to release sweat. Sweat evaporates from the skin surface, which results in heat loss. During exercise and emotional or mental stress, sweating is one way to lose excessive heat produced by the increased metabolic rate.

Diaphoresis is visible perspiration, which occurs primarily on the forehead and upper thorax, although it can be seen elsewhere on the body. Excessive evaporation can cause skin scaling and itching, as well as drying of the nares and pharynx. Lowered body temperature inhibits sweat gland secretion. People who have a congenital absence of sweat glands or a serious skin disease that impairs sweating are unable to tolerate warm temperatures because they cannot cool themselves adequately.

Skin in Temperature Regulation. The skin regulates temperature through insulation of the body, vasoconstriction (which affects the amount of blood flow and heat loss to the skin), and temperature sensation. The skin, subcutaneous tissue, and fat keep heat inside the body. When blood flow between skin layers is reduced, the skin alone is an excellent insulator. People with more body fat have more natural insulation than do slim and muscular people.

In the human body, the internal organs produce heat. During exercise or increased sympathetic stimulation, the amount of heat produced is greater than the usual core temperature. Blood flows from the internal organs, carrying heat to the body surface. The skin is well supplied with blood vessels, especially the areas of the hands, feet, and ears. Blood flow through these vascular areas of skin may vary from minimal flow to as much as 30% of the blood ejected from the heart. Heat transfers from the blood through vessel walls to the skin's surface and is lost to the environment through the heat-loss mechanisms. The body's core temperature remains within safe limits.

The degree of vasoconstriction determines the amount of blood flow and heat loss to the skin. If the core temperature is too high, the hypothalamus inhibits vasoconstriction. As a result, blood vessels dilate, and more blood reaches the skin's surface. On a hot, humid day, the blood vessels in the hands are dilated and easily visible. In contrast, if the core temperature becomes too low, the hypothalamus initiates vasoconstriction and blood flow to the skin lessens, thus conserving body heat.

Behavioural Control. Healthy individuals voluntarily act to maintain a comfortable body temperature when exposed to temperature extremes. A person's ability to control body temperature depends on (1) the degree of temperature extreme, (2) the person's ability to sense feeling comfortable or uncomfortable, (3) thought processes or emotions, and (4) the person's mobility or ability to remove or add clothes. Body temperature control is difficult if any of these abilities is absent. Infants can sense uncomfortably warm conditions but cannot change their environment. Older adults may need assistance in detecting cold environments and minimizing heat loss. Illness, altered levels of consciousness, or impaired thought processes result in an inability to recognize the need to change behaviour for temperature control. In extreme temperatures, health-promoting behaviours such as removing or adding clothing, have a limited effect on controlling temperature. It is important for the nurse to assess for factors that place patients at high risk for ineffective thermoregulation.

Factors Affecting Body Temperature

Many factors affect body temperature. Changes in body temperature within an acceptable range occur when the relationship between heat production and heat loss is altered by physiological or behavioural variables. Be aware of these factors when assessing temperature variations and evaluating deviations from normal.

Age. At birth, the newborn leaves a warm, relatively constant environment and enters one in which temperatures fluctuate widely. Temperature-control mechanisms are immature. An infant's temperature may respond dramatically to changes in the environment requiring extra care to protect the newborn. Body coverings must be adequate, and exposure to temperature extremes must be avoided. A newborn loses up to 30% of body heat through the head and therefore needs to wear a cap to prevent heat loss. When protected from environmental extremes, the newborn's core and peripheral body temperature can be normally maintained between 35.5°C and 37.5°C.

Temperature regulation is unstable until children reach puberty. The normal temperature range gradually drops as individuals approach older adulthood. Older adults have a lower and narrower range of body temperatures than do younger adults. An oral temperature of 35°C is not unusual for

older adults in cold weather. However, the average body temperature of older adults is approximately 36°C . Older adults are particularly sensitive to temperature extremes because of deterioration in control mechanisms, particularly poor vasomotor control (control of vasoconstriction and vasodilation), reduced amounts of subcutaneous tissue, reduced sweat gland activity, and reduced metabolism.

Exercise. Muscle activity requires increases in blood supply and in carbohydrate and fat breakdown. This increased metabolism causes an increase in heat production. Any form of exercise can increase heat production and thus body temperature. Prolonged strenuous exercise, such as long-distance running, can temporarily raise body temperatures up to 41°C .

Hormone Level. Women generally experience greater fluctuations in body temperature than men. Hormonal variations in progesterone during the menstrual cycle cause body temperature fluctuations. When progesterone levels are low, the body temperature is a few tenths of a degree below the baseline level. This lower temperature persists until ovulation occurs. During ovulation, greater amounts of progesterone enter the circulatory system and raise the body temperature to previous baseline levels or higher. These temperature variations can be used to predict a woman's most fertile time to achieve pregnancy.

Body temperature changes also occur during menopause (cessation of menstruation). Menopausal women may experience times of intense body heat and sweating, lasting anywhere from 30 seconds to 5 minutes. Skin temperature may increase intermittently by up to 4°C , which is known as a *hot flash*. These increases in temperature result from the instability of the vasomotor controls for vasodilation and vasoconstriction.

Circadian Rhythm. Body temperature normally changes 0.5°C to 1°C during a 24-hour period. In persons who are awake during the day and sleep during the night, the temperature is usually lowest between 0100 and 0400 hours (Figure 30-2). During the day, body temperature rises steadily, until a maximum temperature value is reached at about 1800 hours, and then declines back down to early morning levels. It takes one to three weeks for temperature patterns to reverse in people who work at night and sleep during the day. In general, the circadian temperature rhythm does not change with age.

Stress. Physical and emotional stress increases body temperature through hormonal and neural stimulation. These

Figure 30-2 Temperature cycle for 24 hours.

physiological changes increase metabolism, which increases heat production. The patient who is anxious about entering a hospital or undergoing a procedure may register a higher normal temperature.

Environment. Environment influences body temperature. If body temperature is measured in a very warm room, a patient may be unable to regulate body temperature by heat-loss mechanisms, resulting in the elevation of body temperature. If the patient has just been outside in the cold without warm clothing, body temperature may be low because of extensive radiant and conductive heat loss. Infants and older adults are most likely to be affected by environmental temperatures because their temperature-regulating mechanisms are less efficient.

Temperature Alterations. Body temperatures outside the usual range affect the hypothalamic set point. Such changes can be related to excess heat production, excessive heat loss, minimal heat production, minimal heat loss, or any combination of these alterations. The nature of the change affects the type of clinical problems experienced.

Fever. Pyrexia, or fever, occurs because heat-loss mechanisms are unable to keep pace with excess heat production; as a result, body temperature rises to an abnormal level. A fever is usually not harmful if it stays below 39°C , keeping in mind that a single temperature reading may not indicate a fever. In addition to physical signs and symptoms of infection, determination of fever is based on several temperature readings at different times of the day that are compared with the usual value for that person at those times.

A true fever results from an alteration in the hypothalamic set point. **Pyrogens** such as bacteria and viruses cause a rise in body temperature. Pyrogens act as antigens, triggering immune system responses. The hypothalamus reacts to raise the set point, and the body responds by producing and conserving heat. Several hours may pass before the body temperature reaches the new set point. During this period, the person experiences chills, shivers, and feels cold, even though the body temperature is rising (Figure 30-3). The chill phase resolves when the new set point, a higher temperature, is achieved. During the next phase, the plateau, the chills subside, and the person feels warm and dry. If the new set point is

Figure 30-3 Effect of changing the set point of the hypothalamic temperature control during a fever. **Source:** Adapted from Hall, J. E. (2011). *Guyton & Hall textbook of medical physiology* (12th ed., p. 876). Philadelphia, PA: W. B. Saunders.

“overshot” or the pyrogens are removed (e.g., destruction of bacteria by antibiotics), the third phase of a febrile episode occurs. The hypothalamus set point drops, initiating heat loss responses. The skin becomes warm and flushed because of vasodilation. Diaphoresis assists in evaporative heat loss. When the fever “breaks,” the person becomes **afebrile**.

Fever is an important defence mechanism. Temperature elevations up to 38°C enhance the body’s immune system. During a **febrile** episode, white blood cell production is stimulated. Increased temperature reduces the concentration of iron in the blood plasma, suppressing the growth of bacteria. Fever also fights viral infections by stimulating production of interferon, the body’s natural virus-fighting substance.

By analyzing a fever pattern, health care providers can make diagnoses. Fever patterns differ, depending on the causative pyrogen. The increase or decrease in pyrogen activity results in fever spikes and declines at different times of the day. The duration and degree of fever depend on the strength of the pyrogen and the ability of the individual to respond. The term **fever of unknown origin** refers to a fever that does not have a determined cause.

During a fever, cellular metabolism increases and oxygen consumption rises. The body’s metabolism increases 10% for every degree Celsius of temperature elevation (Henker & Carlson, 2007). Heart and respiratory rates increase to meet the metabolic needs of the body for nutrients. The increased metabolism entails the use of energy that produces additional heat. If the patient has a cardiac or respiratory problem, the stress of a fever can be great. A prolonged fever can weaken a person by exhausting energy stores. Increased metabolism requires additional oxygen. If the demand for additional oxygen cannot be met, cellular hypoxia (inadequate oxygenation) occurs. Myocardial hypoxia produces angina (chest pain); cerebral hypoxia produces confusion. Interventions during a fever may include oxygen therapy. Water loss through increased respiration and diaphoresis can be excessive, placing a patient at risk for fluid volume deficit. Dehydration is a serious problem for older adults and for children with low body weight. Maintaining optimum fluid volume status is an important nursing intervention (see Chapter 39).

Hyperthermia. **Hyperthermia** is body temperature that is elevated as a result of the body’s inability to promote heat loss or reduce heat production. Whereas fever is an upward shift in the set point, hyperthermia results from an overload of the body’s thermoregulatory mechanisms. Any disease or trauma to the hypothalamus can impair heat-loss mechanisms. **Malignant hyperthermia** is a hereditary condition of uncontrolled heat production, occurring when susceptible individuals receive particular anaesthetic medications that trigger a sudden and potentially severe hyperthermic response requiring urgent intervention (Hernandez, et al., 2009).

Heatstroke. Prolonged exposure to the sun or high environmental temperatures can overwhelm the body’s heat-loss mechanisms. Heat also depresses hypothalamic function. These conditions cause **heatstroke**, a dangerous heat emergency with a high mortality rate. Patients at risk include the very young, the elderly, and those who have cardiovascular disease, hypothyroidism, diabetes, or alcoholism. Also at risk are patients who take medications that decrease the body’s ability to lose heat (e.g., phenothiazines, anticholinergics, diuretics, amphetamines, and β -adrenergic receptor antagonists) and those who exercise or engage in strenuous physical labour (e.g., athletes, construction workers, and farmers).

► TABLE 30-1 Classification of Hypothermia

Description	Temperature (°C)
Mild	34–36
Moderate	30–34
Severe	<30

Signs and symptoms of heatstroke include confusion, delirium, excess thirst, nausea, muscle cramps, visual disturbances, giddiness, and incontinence. The most important sign is hot, dry skin. Patients with heatstroke do not sweat because of severe electrolyte loss and hypothalamic malfunction. Vital signs reveal a body temperature sometimes as high as 45°C, with an increase in heart rate and lowering of blood pressure. If the condition progresses, unconsciousness can occur. Permanent neurological damage may result unless cooling measures are rapidly started.

Heat Exhaustion. **Heat exhaustion** occurs when profuse diaphoresis results in excessive water and electrolyte loss. The patient exhibits signs and symptoms of fluid volume deficit (see Chapter 39). Treatment includes transporting the patient to a cooler environment and restoring fluid and electrolyte balance.

Hypothermia. Heat loss during prolonged exposure to cold overwhelms the body’s ability to produce heat, causing hypothermia. **Hypothermia** is classified by core temperature measurements (Table 30-1). It can be unintentionally induced (e.g., by falling through the ice of a frozen lake) or intentionally induced (e.g., during specific surgical procedures) to reduce metabolic demand and the body’s need for oxygen. Accidental hypothermia usually develops gradually and may go unnoticed for several hours. When body temperature drops to 35°C, uncontrolled shivering, loss of memory, depression, and poor judgement occur. As the body temperature falls below 34.4°C, heart rate, respiratory rate, and blood pressure fall and the skin becomes cyanotic. If hypothermia progresses, cardiac dysrhythmias, loss of consciousness and unresponsiveness to painful stimuli occur. In cases of severe hypothermia, clinical signs similar to death (e.g., lack of response to stimuli and extremely slow respirations and pulse) are demonstrated. The assessment of core temperature is critical when hypothermia is suspected. A special thermometer that displays low readings may be required because most standard devices do not register below 35°C.

Frostbite occurs when the body is exposed to subnormal temperatures. Ice crystals forming inside cells can result in permanent circulatory and tissue damage. Areas on the body particularly susceptible to frostbite are the earlobes, tip of the nose, fingers, and toes. The injured area becomes white, waxy, and firm to the touch and loss of sensation occurs in the affected area. Intervention includes gradual warming measures, analgesia, and protection of the injured tissue.

Nursing Process and Thermoregulation

Knowledge of the physiology of body temperature regulation is essential for assessing and evaluating the patient’s response to temperature alterations and for intervening safely. Independent measures can be implemented to increase or minimize heat loss, promote heat conservation, and increase comfort. These measures complement the effects of medically ordered therapies. Many measures can be taught to family members, parents of children, and other caregivers.

❖ Assessment

Sites

Core and surface body temperature may be measured at several sites. The core temperatures of the pulmonary artery, esophagus, and urinary bladder are measured in intensive care settings. These measurements require the use of invasive devices placed in body cavities or organs that continuously display readings on an electronic monitor.

Intermittent temperature measurements are obtained invasively from the sites of the mouth, rectum, and tympanic membrane or noninvasively from the axilla and temporal artery sites. Chemically prepared thermometer patches can also be applied to the skin. In order to measure oral, rectal, axillary,

and skin temperature, blood circulation at the measurement site must be effective so that the heat of the blood is conducted to the thermometer probe. Tympanic temperature relies on the radiation of body heat to an infrared sensor. Temporal artery measurements detect cutaneous blood flow temperature (Pompei, 1999). Because they share the same arterial blood supply as the hypothalamus, tympanic and temporal artery temperature measurements can be considered core temperatures (Purssell et al., 2009).

Correct measuring technique must be used at each site (Skill 30-1) to ensure accurate readings. The temperature obtained varies according to the site used but should remain between 36.0°C and 38.0°C. Rectal temperatures are usually 0.5°C

► SKILL 30-1 Measuring Body Temperature

Delegation Considerations

The task of measuring temperature can be delegated to unregulated care providers (UCPs). The nurse is responsible for assessing the impact of changes in body temperature; therefore, when the task of measuring temperature is delegated, it is important to *inform the unregulated care provider* about the following:

- The appropriate route and device to measure temperature
- Patient-specific factors that can falsely raise or lower temperature
- Appropriate precautions when positioning the patient
- Frequency of temperature measurement for the patient
- Usual values for patient
- Abnormalities that should be reported to the health care provider

Equipment

- Appropriate thermometer
- Soft tissue or wipe
- Alcohol swabs
- Lubricant (for rectal measurements only)
- Pen and either vital sign flow sheet or documentation form
- Disposable gloves
- Plastic thermometer sleeve or disposable probe cover

Procedure

STEPS

1. Assess for signs and symptoms of temperature alterations and for factors that influence body temperature.
2. Determine previous activity that would interfere with accuracy of temperature measurement. Wait before measuring oral temperature in the following situations: 2 minutes after patient has smoked, 5 minutes after patient has chewed gum, and 20 minutes after patient has ingested hot or cold liquids or foods.
3. Determine appropriate temperature site and device for patient.
4. Explain to patient the route by which temperature will be measured and the importance of maintaining proper position until the reading is complete.
5. Perform hand hygiene.
6. Obtain temperature reading.
 - A. Oral temperature measurement with electronic thermometer
 - (1) Put on disposable gloves (optional).
 - (2) Remove thermometer pack from charging unit. Attach oral probe (blue tip) to thermometer unit. Grasp top of probe stem, being careful not to press the ejection button.

RATIONALE

- Physical signs and symptoms may indicate abnormal temperature. You can accurately assess the nature of variations.
- Smoking, mouth breathing, and oral intake of food or fluids can cause false oral temperature readings (Henker & Carlson, 2007).
- This choice is based on advantages and disadvantages of each site (see Box 30-4) (Mains et al., 2008). Use a disposable, single-use thermometer for a patient who has isolation precautions.
- Patients are often curious about measurements and should be cautioned against prematurely removing the thermometer to read results.
- Hand hygiene reduces transmission of microorganisms between the patient and the nurse.
- Use of oral probe cover, removed without physical contact minimizes need to wear gloves.
- Charging provides battery power. Removal of hand-held unit from base prepares it to measure temperature. Pressing ejection button releases plastic probe cover from tip.

video

- (3) Slide disposable plastic probe cover over thermometer probe until cover locks in place (see Step 6A[3] illustration).
 - (4) Have patient sit or lie in bed. Ask patient to open mouth; gently place thermometer probe under patient's tongue in posterior sublingual pocket lateral to centre of lower jaw (see Step 6A[4] illustration).
- Soft plastic cover will not break in patient's mouth and it prevents transmission of microorganisms between patients.
 - Heat from superficial blood vessels in sublingual pocket produces temperature reading. Temperatures in right and left posterior sublingual pockets are significantly higher than in area under front of tongue.

**Step 6A(3)** Inserting thermometer stem into plastic probe cover.**Step 6A(4)** Probe under tongue in posterior sublingual pocket.

- (5) Ask patient to hold thermometer probe with lips closed.
 - (6) Leave thermometer probe in place until audible signal occurs and patient's temperature appears on digital display; remove thermometer probe from under patient's tongue.
 - (7) Push ejection button on thermometer stem to discard plastic probe cover into appropriate receptacle.
 - (8) Return thermometer stem to storage well of recording unit.
 - (9) If gloves were worn, remove and dispose in appropriate receptacle. Perform hand hygiene.
 - (10) Return thermometer to charger.
- B. Rectal temperature measurement with electronic thermometer**
- (1) Prepare patient for procedure.
 - (a) Draw curtain around patient's bed or close room door, or do both.
 - (b) Assist patient in a side-lying or Sims' position with upper leg flexed.
 - (c) Move aside bed linen to expose only anal area. Keep patient's upper body and lower extremities covered with sheet or blanket.
 - (d) Remind patient to remain in position until procedure is complete.
 - (2) Put on disposable gloves.
 - (3) Remove thermometer pack from charging unit. Attach rectal probe (red tip) to thermometer unit. Grasp top of probe stem, being careful not to press the ejection button.
 - (4) Slide disposable plastic probe cover over thermometer probe until cover locks in place.
 - (5) Squeeze liberal portion of lubricant on tissue. Dip thermometer's blunt end into lubricant, covering 2.5–3.5 cm for adult patient or 1.2–2.5 cm for infant/child.
 - (6) With nondominant hand, separate patient's buttocks to expose anus. Ask patient to breathe slowly and relax.
 - (7) Gently insert thermometer into patient's anus in direction of umbilicus, 3.5 cm for adult patient. Do not force thermometer.
 - (8) If resistance is felt during insertion, withdraw thermometer.
- Holding the probe this way helps maintain proper position of thermometer during recording.
 - Probe must stay in place until signal occurs, to ensure accurate reading.
 - Discarding probe cover reduces transmission of microorganisms between patients.
 - Proper storage protects probe from damage. Returning probe automatically causes digital reading to disappear.
 - Glove disposal and hand hygiene reduce transmission of microorganisms between patients.
 - Charging provides battery power.
 - Provides appropriate access for insertion of rectal probe.
 - These actions maintain patient's privacy, minimize embarrassment, and promote comfort. Anal area is exposed for correct thermometer placement.
 - Gloves help maintain standard precautions during exposure to items soiled with body fluids (e.g., feces).
 - Charging provides battery power. Removal of hand-held unit from base prepares it to measure temperature. Pressing the ejection button releases plastic probe cover from tip.
 - Probe cover prevents transmission of microorganisms between patients.
 - Lubrication minimizes trauma to rectal mucosa during thermometer insertion. Tissue avoids contamination of remaining lubricant in container.
 - Separating buttocks fully exposes anus for thermometer insertion. Relaxing anal sphincter facilitates thermometer insertion.
 - Insertion in this direction ensures adequate exposure against blood vessels in rectal wall.
 - This action prevents trauma to mucosa.

► SKILL 30-1 Measuring Body Temperature—cont'd

Critical Decision Point: If thermometer cannot be adequately inserted into rectum, remove thermometer and consider alternative method for obtaining temperature.

- (9) Once positioned, thermometer probe should be left in place (see Step 6B[9] illustration) until audible signal occurs and patient's temperature appears on digital display; remove thermometer probe from anus.
- Probe must stay in place until signal occurs, to ensure accurate reading.

Step 6B(9) Probe positioned in anus.

- (10) Push ejection button on thermometer stem to discard plastic probe cover into appropriate receptacle. Wipe probe adequately with alcohol swab, paying particular attention to ridges where probe cover is connected to probe.
 - (11) Return thermometer stem to storage well of recording unit.
 - (12) Wipe patient's anal area with soft tissue to remove lubricant or feces, and discard tissue. Assist patient to assume a comfortable position and sufficiently covered with linens.
 - (13) Remove and dispose of gloves in appropriate receptacle. Perform hand hygiene.
 - (14) Return thermometer unit to charger. Verify that charger and probes are wiped with alcohol daily (in isolation areas, they are wiped whenever they are removed from the room).
 - Discarding probe cover reduces transmission of microorganisms between patients.
 - Proper storage protects probe from damage. Returning probe automatically causes digital reading to disappear.
 - These actions provide for comfort and hygiene.
- C. Axillary temperature measurement with electronic thermometer**
- (1) Prepare patient for procedure.
 - (a) Draw curtain around patient's bed or close room door, or do both.
 - (b) Assist patient to a supine or sitting position.
 - (c) Move clothing or gown away from patient's shoulder and arm.
 - (2) Remove thermometer pack from charging unit. Ensure oral probe (blue tip) is attached to thermometer unit. Grasp top of probe stem, being careful not to press the ejection button.
 - (3) Slide disposable plastic probe cover over thermometer probe until cover locks in place.
 - Glove disposal and hand hygiene reduce transmission of microorganisms between the patient and the nurse.
 - Charging provides battery power. Wiping with alcohol reduces transmission of microorganisms between the patient and the nurse.
 - These actions maintain patient's privacy, minimize embarrassment, and promote comfort.
 - These positions enable easy access to axilla.
 - This action exposes axilla for correct thermometer probe placement.
 - Charging provides battery power. Removal of hand-held unit from base prepares it to measure temperature. Pressing ejection button releases plastic cover from probe.
 - Soft plastic cover prevents transmission of microorganisms between patients.

Continued

► SKILL 30-1 Measuring Body Temperature—cont'd

video

- (4) Raise patient's arm away from torso; inspect for skin lesions and excessive perspiration. Insert probe into centre of patient's axilla, lower patient's arm over probe, and place arm across patient's chest (see Step 6C[4] illustration).
- Maintains proper position of probe against blood vessels in axilla.

Step 6C(4) Thermometer tip in axilla.

Critical Decision Point: Do not use axilla if skin lesions are present because local temperature may be altered and area may be painful to touch. Wipe off excessive perspiration.

- (5) Hold probe in place until audible signal occurs and temperature appears on digital display.
 - (6) Remove probe from patient's axilla.
 - (7) Push ejection button on thermometer stem to discard plastic probe cover into appropriate receptacle.
 - (8) Return thermometer stem to storage well of recording unit.
 - (9) Assist patient to assume a comfortable position, and move linen or gown back over patient's shoulder.
 - (10) Perform hand hygiene.
 - (11) Return thermometer to charger.
- D. Tympanic membrane temperature measurement with electronic thermometer**
- (1) Assist patient in assuming comfortable position with head turned to side, away from nurse. Right-handed caregivers should obtain temperature from patient's right ear. Left-handed caregivers should obtain temperature from patient's left ear.
 - (2) Check for the presence of obvious cerumen in the patient's ear canal.
 - (3) Remove thermometer hand-held unit from charging base, being careful not to press the ejection button.
 - (4) Slide clean disposable speculum cover over otoscope-like lens tip until it locks into place; be careful not to touch lens cover.
 - (5) Insert speculum into patient's ear canal in accordance with manufacturer's instructions for tympanic probe positioning:
 - (a) Pull patient's pinna backward, up, and out. For children younger than 2 years, pull pinna backward and point covered speculum tip toward midpoint between eyebrow and sideburn.
- Probe must stay in place until signal occurs, to ensure accurate reading.
 - Discarding probe cover reduces transmission of microorganisms between the patient and the nurse.
 - Proper storage protects probe from damage. Returning probe automatically causes digital reading to disappear.
 - Restores comfort and promotes privacy.
 - Hand hygiene reduces transmission of microorganisms between the patient and the nurse.
 - Charging provides battery power.
 - This positioning ensures comfort and exposes auditory canal for accurate temperature measurement. The less acute the angle of approach, the better the probe seal.
 - To ensure clear optical pathway, lens cover of speculum must not be impeded by cerumen. Switch to other ear or select alternative measurement site if necessary.
 - Charging provides battery power. Removal of hand-held unit from base prepares it to measure temperature. Pressing ejection button releases plastic probe cover from tip.
 - Lens cover must be clear of dust, fingerprints, and cerumen to ensure clear optical pathway.
 - Correct positioning of the probe with regard to ear canal ensures accurate readings. Operator errors cause false readings.
 - Ear tug straightens the external auditory canal, allowing maximum exposure of the tympanic membrane (Hockenberry & Wilson, 2007).

► SKILL 30-1 Measuring Body Temperature—cont'd**video**

- (b) Fit otoscope probe snugly into canal and do not move (see Step 6D[5][b] illustration).

- Gentle pressure seals ear canal from ambient temperature, which can alter readings as much as 2.8°C.

Step 6D(5)(b) Tympanic thermometer with probe cover inserted into auditory canal.

- (c) Point speculum tip toward patient's nose.
 - (6) When probe is in place, press scan button on hand-held unit. Leave thermometer probe in place until audible signal occurs and patient's temperature appears on digital display.
 - (7) Carefully remove speculum from auditory canal.
 - (8) Push ejection button on hand-held unit to discard plastic probe cover into appropriate receptacle.
 - (9) If a second reading is necessary, replace probe lens cover and wait 2 to 3 minutes before inserting probe tip.
 - (10) Return hand-held unit to charging base.
 - (11) Assist patient to assume a comfortable position.
 - (12) Perform hand hygiene.
7. Discuss findings with patient as needed.
 8. If patient's temperature is being assessed for the first time and is within normal range, document temperature as baseline.
 9. Compare current temperature reading with patient's previous baseline and with acceptable temperature range for patient's age group.
- When scan button is pressed, probe detects infrared energy. Otoscope tip must stay in place until signal occurs, to ensure accurate reading.
 - Careful removal prevents rubbing of sensitive outer ear lining.
 - Discarding probe cover reduces transmission of microorganisms between the patient and the nurse and automatically causes digital reading to disappear.
 - Lens cover must be free of cerumen to maintain optical path. Time allows auditory canal to regain usual temperature.
 - Proper storage protects probe from damage.
 - This action restores comfort and sense of well-being.
 - Hand hygiene reduces transmission of microorganisms between the patient and the nurse.
 - Such discussion promotes patient's participation in care and understanding of health status.
 - Baseline is used to compare future temperature measurements.
 - Normal body temperature fluctuates within narrow range; comparison helps reveal presence of abnormality. Improper placement or movement of thermometer causes inaccuracies. Second measurement confirms initial findings of abnormal body temperature.

Unexpected Outcomes

Temperature 1°C above usual range

Persistent fever

Temperature 1°C below usual range

Related Interventions

- Assess possible sites (e.g., central line catheter, wounds) for localized infection and for related data suggestive of a systemic infection.
- Implement appropriate nursing measures (see Box 30-10).
- Notify appropriate health care provider and administer antipyretic and antibiotics as prescribed.
- Remove any drafts, wet clothing, or damp linens.
- Apply extra blankets, and, unless contraindicated, offer warm liquids.

Recording and Reporting

- Record temperature on vital sign flow sheet. Document temperature after administration of specific therapies in nurses' narrative notes.
- Report abnormal findings to nurse in charge or to prescribing health care provider.

Home Care Considerations

- Assess temperature and ventilation of patient's environment to determine existence of any environmental condition that may influence outcome of patient's temperature.
- In the home, patients may continue to use mercury-in-glass thermometers (see Box 30-6). Assess whether the storage of these thermometers is adequate to protect them from breakage and to prevent mercury spills. Educate patient and caregiver about mercury hazards.

higher than oral temperatures, and axillary temperatures are usually 0.5°C lower than oral temperatures. Each measurement site has advantages and disadvantages (Box 30-4). The rectal site was traditionally chosen due to the close replication of core body temperature but is now less routinely measured

given the availability of less invasive and accurate alternative measurement devices such as the temporal thermometer. Choose the safest and most effective site for each patient. When possible, use the same site when measurements must be repeated.

► BOX 30-4 Advantages and Disadvantages of Select Temperature Measurement Sites

Tympanic Membrane

Advantages

- Site is easily accessible; minimal patient repositioning is required.
- Temperature reading can be obtained without disturbing or waking patient.
- Device provides core reading, as the eardrum is close to the hypothalamus.
- Measurement is very rapid (2 to 5 seconds).
- Measurement is unaffected by oral intake of food or fluids or by smoking.
- Device can be used for tachypneic patients without affecting breathing.
- Device can be used in newborns to reduce handling of infants and subsequent heat loss.

Disadvantages

- Measurement is more variable with this device than with other core temperature devices.
- Hearing aids must be removed before measurement.
- Site cannot be used in patients following surgery of the ear or tympanic membrane.
- Readings are altered by cerumen impaction and otitis media.
- Disposable probe cover comes in only one size.
- Device does not accurately measure core temperature changes during and after exercise.
- Positioning the device correctly in newborns, infants, and children younger than three years is challenging because of the anatomy of the ear canal (Holtzclaw, 2003).
- Inaccuracies can result from incorrect positioning of unit (Maxton et al., 2004).
- Obtaining continuous measurement is not possible.
- Temperature readings are affected by ambient temperature devices such as incubators, radiant warmers, and fans.

Rectum

Advantages

- Site is argued to be more reliable when oral temperature cannot be obtained.

Disadvantages

- Measurement at this site lags behind those at sites of core temperature during rapid temperature changes (Maxton et al., 2004).
- Site should not be used in patients with diarrhea, rectal surgery, a rectal disorder, or bleeding tendencies.
- Site should not be used for routine measurement of vital signs in newborns.
- Given the invasiveness of this approach and the positioning that is required, this may be a source of patient discomfort, embarrassment, and anxiety.
- Impacted stool alters readings (Maxton et al., 2004).
- Measurement at this site carries risk of exposure to body fluids.
- Lubrication is required.

Mouth

Advantages

- Site is accessible, and no position change is required.
- Measurement is comfortable for patients.

- Measurement provides accurate reading of surface temperature.
- Measurement reflects rapid change in core temperature.

Disadvantages

- Readings are affected by ingestion of fluids or foods, smoking, and oxygen delivery.
- Not suitable for patients who have had oral surgery, have suffered trauma, have a history of epilepsy, or have shaking chills.
- Site should not be used for infants and small children or in confused, unconscious, or uncooperative patients.
- Measurement at this site carries risk of exposure to body fluids.

Axilla

Advantages

- Safe and noninvasive
- Appropriate for use in newborns and in uncooperative or unconscious patients.

Disadvantages

- Measurement time is long.
- Measurement at this site necessitates continuous positioning by nurse.
- Measurement time lags behind those at sites of core temperature during rapid temperature changes.
- Requires exposure of thorax, which can result in temperature loss, especially in newborns.
- Readings are affected by exposure to environment during device placement (Maxton et al., 2004).
- Not recommended for detecting fever in infants and young children.

Skin

Advantages

- Continuous reading can be obtained.
- Safe and noninvasive.
- Requires minimal disturbance to patient.
- Appropriate site for newborn measurement.

Disadvantages

- Measurement time lags behind those at other sites during temperature changes, especially during hyperthermia.
- Adhesion of the thermometer can be impaired by diaphoresis or sweat.
- Measurement at this site can be affected by environmental temperature.
- Cannot be used for patients who have allergy to adhesive.

Temporal Artery

Advantages

- Measurement is rapid.
- Measurement reflects rapid change in core temperature.
- Site is easy to access without changing the patient's position.
- Measurement is comfortable and eliminates need to remove clothing.
- Measurement is useful in premature infants, newborns, and children.

Disadvantages

- Measurement is not effective through head covering (e.g., dressing) or hair.
- Results are affected by diaphoresis or sweating.
- Continuous measurement is not possible.

Figure 30-4 Electronic thermometer. The blue probe is for oral or axillary use. The red probe is for rectal use.

Thermometers

Two types of thermometers are commonly available for measuring body temperature: electronic and disposable. A third type, the mercury-in-glass thermometer, was once the standard device for the clinical setting. Most municipalities have now prohibited the sale or use of mercury-containing medical devices because of potential toxins associated with mercury spills in addition to the potential hazards associated with glass breakage during temperature measurement.

Temperature is recorded according to the **Celsius** scale. Electronic thermometers allow conversion to alternative scales by activating a switch.

Electronic Thermometer. The electronic thermometer consists of a rechargeable battery-powered display unit, a thin wire cord, and a temperature-processing probe covered by a disposable plastic cover (Figure 30-4). Separate unbreakable probes are available for oral and rectal use. The oral probe can also be used for axillary temperature measurement. Electronic thermometers provide two modes of operation: a 4-second predictive temperature and a 3-minute standard temperature. When the first mode is used, a reading appears on the display unit within 20 to 50 seconds of insertion. A signal is sounded when the peak temperature reading has been measured.

Another form of electronic thermometer is used exclusively for tympanic temperature. An otoscope-like speculum with an infrared sensor tip detects heat radiated from the tympanic membrane. Within two to five seconds after the speculum is placed in the auditory canal, a reading appears on the display unit. A signal is sounded when the peak temperature reading has been measured.

Newer to the market is an electronic thermometer that measures the temperature of the superficial temporal artery. A hand-held scanner with an infrared sensor tip detects the temperature of cutaneous blood flow: the sensor is swept across the forehead and just behind the ear (Figure 30-5). Once scanning is complete, a reading appears on the display. Temporal artery temperature is a reliable and noninvasive measure of core temperature and has become an institutional standard in many health care settings (Box 30-5).

The greatest advantages of electronic thermometers are that they can be used immediately and read easily within seconds. The plastic sheath is unbreakable, making these devices ideal for use in children. Their expense is a major disadvantage.

Figure 30-5 Temporal artery thermometer scanning the child's forehead.

► BOX 30-5 Procedural Guideline

Measurement of Temporal Artery Temperature

Delegation Considerations:

The measurement of temporal artery temperature can be delegated to unregulated care providers. The nurse is responsible for assessing the impact of changes on body temperature; therefore, when measurement of temporal artery temperature is delegated, it is important to *inform the unregulated care provider* about the following:

- Frequency of temperature measurement
- Factors that falsely raise or lower temperature readings
- Reporting abnormalities to the nurse for further assessment

Equipment:

Temporal artery thermometer, alcohol wipes or probe cover (optional).

Procedure:

1. Perform hand hygiene.
2. Ensure that the patient's forehead is dry; wipe it with towel if it is moist.
3. Place the probe flush on the patient's forehead to avoid measuring ambient temperature.
4. Press the red scan button with your thumb. Scanning for the highest temperature will be continuous until you release the scan button.
5. Slowly slide the thermometer straight across the patient's forehead while keeping the probe flush on the patient's skin.
6. Keeping scan button pressed, lift the probe from the patient's forehead, and touch the probe to the patient's neck just behind the earlobe (the area where perfume is typically applied).
7. While the probe is scanning, a clicking sound occurs; this sound stops when peak temperature is scanned.
8. Release the scan button; read and record the temperature. Reading remains on screen for 15 seconds after the button is released.
9. Clean the probe with an alcohol wipe, or, if a probe cover was used, remove and dispose of the probe cover.

Maintaining cleanliness of the probes is important. If a rectal probe is not properly cleaned between patients, contamination of the rectal probe by gastrointestinal disease organisms can be a vector of disease transmission. The thermometer must be wiped frequently with alcohol, and the thermometer probe

Figure 30-6 Disposable, single-use thermometer strip.

must be wiped with an alcohol swab after each use. Particular attention must be paid to the probe hub, which has ridges, where the probe cover is secured to the probe.

Chemical Strip Thermometers. Single-use or reusable chemical strip (or dot) thermometers are thin strips of plastic containing a temperature sensor at one end. The sensor consists of chemically impregnated dots that change colour at different temperatures in increments of 0.1°C between 35.5°C and 40.4°C (Figure 30-6). Most of these devices are intended for single use, but the dots on reusable strips return to their original colour in seconds. The devices are used for measuring oral or axillary temperatures, particularly in children, and may be used rectally in a special sheath. The thermometer is removed after 60 seconds and read after another wait of 10 seconds to ensure that the temperature reading has stabilized. Research has shown that disposable single-use thermometers tend to overestimate or underestimate true temperature readings. The device is recommended only for screening purposes. When an abnormal temperature is suspected, the temperature should be confirmed with an electronic thermometer. The chemical strip thermometers are useful in caring for patients with isolation precautions (see Chapter 32), to avoid the need to take electronic instruments into these patients' rooms.

Another type of disposable thermometer is a temperature-sensitive patch or tape. Applied to the forehead or abdomen, the patch changes colour at different temperatures. These thermometers are also useful for screening patients, especially infants, for altered temperature. If an abnormal temperature is suspected, the temperature must be confirmed with an electronic temperature device. Disposable thermometers are not appropriate for monitoring temperature therapies.

Glass Thermometers. The traditional glass thermometer is a glass tube sealed at one end and with a mercury—or more recently, due to safety factors, an alcohol-filled bulb—at the other end of the device. Exposure of the bulb to heat causes the internal fluid to expand and rise in the enclosed tube. The length of the thermometer is marked with centigrade (Celsius) calibrations from which the temperature reading is obtained. The thermometer must be positioned properly at the oral, rectal, or axillary site and must be maintained for the appropriate length of time to obtain an accurate reading (Box 30-6). There are many disadvantages to the use of this type of device. In addition to the time delay (approximately three minutes with the device held in place), the mercury-in-glass device is easily breakable and, when broken, releases the contents, which may include hazardous mercury (Box 30-7). With the potent toxicities associated with mercury spills, in addition to

► BOX 30-6 Procedural Guideline

Use of a Glass Thermometer

Delegation Considerations:

Patient, family, or unregulated care provider will safely perform temperature measurement.

Equipment:

Glass thermometer (rectal or oral), plastic sleeve, lubricating jelly (rectal only), disposable gloves.

Procedure:

1. Perform hand hygiene. Apply disposable gloves to avoid contact with body fluids (e.g., saliva, stool).
2. Hold the nonbulbed end of the glass thermometer (if colour-coded, tip will be blue or red) with your fingertips to reduce contamination of the bulb.
3. Read the internal fluid level while gently rotating the thermometer at eye level. If the fluid is above the desired level, grasp the tip of the thermometer securely, stand away from solid objects, and sharply flick your wrist downward. Brisk shaking lowers the fluid level in the glass tube. Continue shaking the thermometer until the reading is below 35.6°C . The thermometer reading must be lower than the patient's actual temperature before the thermometer is used.
4. Insert the thermometer into a plastic sleeve cover, if available, to protect it from body secretions (e.g., saliva, stool). For rectal use, apply lubricant to cover 2.5 cm to 3.5 cm of the rectal thermometer.
5. Place the thermometer according to the technique appropriate for the oral, rectal, or axillary site (see Skill 30-1).
6. Leave the thermometer in place three minutes for oral or rectal temperature, five minutes for axillary temperature, or according to agency policy.
7. Remove the thermometer. Carefully discard the plastic sleeve. Wipe off secretions with a clean tissue, moving toward the bulb or follow institutional cleaning policies. If the device has been used without a plastic sleeve, ensure the thermometer is cleansed with warm, soapy water or rubbing alcohol after use. Store the thermometer in its storage container. Remove your gloves, and perform hand hygiene.
8. Read the thermometer at eye level. Record the findings. Store the thermometer in its storage container. Remove your gloves, and perform hand hygiene.

injuries from the use of glass thermometers, most health care agencies no longer supply these devices. If a glass thermometer is required, the mercury should be replaced with alcohol or other solutions currently available.

Patients may have mercury-in-glass thermometers in their homes. It is important to teach patients and their families what to do in the event of breakage of a mercury-in-glass thermometer.

❖ Nursing Diagnosis

Identify assessment findings and cluster defining characteristics to form a nursing diagnosis. Nursing diagnoses for patients with body temperature alterations include the following:

- *Risk for imbalanced body temperature*
- *Hyperthermia*
- *Hypothermia*
- *Ineffective thermoregulation*

► BOX 30-7

Steps to Take in the Event of a Mercury Spill

1. Do not touch spilled mercury droplets. If skin contact has occurred, immediately flush area with water for 15 minutes.
2. If possible, remove patient from immediate contaminated environment, and shut door to contaminated area.
3. Using rubber gloves, remove any clothing, linen, or shoes contaminated with mercury, and place these items in a plastic garbage bag.
4. Using rubber gloves, contain visible mercury beads with moistened rags or paper towel. Turn off heating or air conditioning systems that could circulate air from spill site to other areas. Turn down thermostat.
5. Follow procedures for mercury removal outlined by local health authority. Notify environmental services department or occupational health services to obtain a mercury spill kit or instructions.
6. Spills are removed using special absorbent materials, filtered vacuum equipment, and protective clothing. Everything is sealed in plastic to be discarded or cleaned according to Environment Canada (2007) guidelines.
7. Keep area well ventilated for 24 hours.
8. Complete incident report as directed by institution procedure.

Adapted from Environment Canada. (2007). *Cleaning up small mercury spills: Mercury and the environment*. Retrieved from <http://www.ec.gc.ca/mercury/en/cu.cfm>.

For example, an increase in body temperature, flushed skin, skin warm to touch, and tachycardia are indicative of the diagnosis *hyperthermia*. The nursing diagnosis is stated as either an at-risk or an actual temperature alteration. If the patient has risk factors for temperature alterations, minimize or eliminate them.

Once the diagnosis is established, accurately determine the related factor or cause (Box 30-8). The related factor directs the selection of appropriate nursing interventions. In the example of hyperthermia, a related factor of vigorous activity will result in interventions much different from those for a related factor of decreased ability to perspire.

❖ Planning

During planning, integrate knowledge gathered from assessment and patient history to develop an individualized care plan (Box 30-9). Match patient's needs with interventions that are supported and recommended in the clinical research literature.

Goals and Outcomes

The care plan for a patient with alteration in temperature must include realistic and individualized goals along with relevant outcomes. Collaborate closely with the patient in setting goals and outcomes and choosing nursing interventions. Expected outcomes are established to gauge progress toward returning the body temperature to an acceptable range. Goals may be short term, such as regaining normal range of body temperature in 24 hours, or long term, such as helping the patient modify the environment, (e.g., obtaining appropriate clothing to wear in cold weather). Outcomes must be related to what is learned about the patient.

► BOX 30-8

NURSING DIAGNOSTIC PROCESS

Assessment Activities	Defining Characteristics	Nursing Diagnosis
Measure vital signs, including temperature, pulse, respirations, and pulse oximetry (SpO ₂).	Increased body temperature above usual range Tachycardia Tachypnea Hypoxemia	Ineffective thermoregulation related to aging and inability to adapt to environmental temperature
Palpate skin.	Warm, dry skin	
Observe patient's appearance and behaviour while talking and resting.	Restlessness Confusion Flushed appearance	
Review medical history.	Location (e.g., found in unventilated apartment during heat wave) and other patient characteristics (e.g., 85 years old with history of dementia)	

Setting Priorities

The severity of temperature alteration and its effects, together with the patient's general health status, influence care priorities. Safety is a top priority. In many cases, other medical problems complicate the care plan. For instance, alterations in body temperature affect the body's requirements for fluids. Patients with cardiac disease may have difficulty tolerating required fluid replacement therapy.

Continuity of Care

Patients at high risk for alterations in body temperature require an individualized care plan directed at maintaining normothermia (normal body temperature) and reducing risk factors. For example, the outcome of care may be that the patient can explain actions to take during a heat wave. Teach the patient and caregiver the importance of thermoregulation and actions to take during very hot weather. Education is particularly important for parents who need to know how to take action at home when an infant or child develops temperature alteration.

❖ Implementation

Health Promotion

Health promotion for patients at risk for altered body temperature is directed toward promoting balance between heat production and heat loss. Patient activity, temperature of the environment, and clothing are all considered. In the prevention of hyperthermia, teach patients to avoid strenuous exercise in hot, humid weather; to drink fluids such as water or clear fruit juices before, during, and after exercise; to wear light, loose-fitting, light-coloured clothes; to avoid exercising

► BOX 30-9 NURSING CARE PLAN

Hyperthermia

Assessment

Mr. Coburn is a 45-year-old teacher who arrives at the outpatient clinic complaining of malaise. His medical history includes a past urinary tract infection. Several of his students have had colds lately. He has been feeling unwell for the past three days.

Assessment Activities

Palpate skin.

Findings and Defining Characteristics

Skin warm and dry to touch

Observe patient's behaviour when talking and resting.

Breathing appears laboured; face is flushed

Measure vital signs.

Blood pressure: right arm, 116/62 mm Hg; left arm, 114/64 mm Hg
Right radial pulse, 128 beats per minute, regular and bounding
Respiratory rate regular at 26 breaths per minute
SpO₂, 98% on room air
Oral temperature, 39.2°C

Review medical history.

Smokes one pack of cigarettes per day and recently began expectorating yellow-green sputum
Tired for past 3 days and dizzy upon rising in the morning

Nursing Diagnosis: Hyperthermia related to infectious process

Planning

Goal (Nursing Outcomes Classification)*

Patient will regain normal range of body temperature within next 24 hours.

Expected Outcomes

Thermoregulation

Body temperature will decline at least 1°C within next 8 hours.
Patient will verbalize increased satisfaction with rest and sleep pattern.

Patient will attain sense of comfort and rest within next 48 hours.

Patient will report increase in energy level within next 3 days.

*Outcome classification label from Moorhead, S., Johnson, M., & Maas, M. L. (2008). *Nursing outcomes classification (NOC)* (4th ed.). St Louis, MO: Mosby.

Interventions (Nursing Interventions Classification)[†]

Fever Treatment

Instruct patient to reduce external coverings and keep clothing and bed linen dry.

Rationale

Heat loss is promoted through conduction and convection.

Instruct patient to monitor temperature at home frequently and take acetaminophen every 4 hours as ordered for temperature higher than 38°C.

Antipyretics reduce set point.

Instruct patient to limit physical activity and increase frequency of rest periods over next 2 days.

Activity and stress increase metabolic rate, contributing to heat production.

[†]Intervention classification label from Dochterman, J. M., Bulechek, G. M., & Butcher, H. K. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St Louis, MO: Mosby.

Evaluation

Nursing Actions

Obtain body temperature measurement.

Patient Response and Finding

Body temperature, 37.8°C

Achievement of Outcome

Body temperature is within normal limits.

Ask Mr. Coburn whether his energy level has changed since the last visit.

He responds, "I am sleeping much better and have returned to work with a lot more energy."

Rest and sleep pattern have improved, and energy level has increased.

in areas with poor ventilation; to wear a protective covering over the head when outdoors; and, when entering hot climates, to expose themselves to the heat gradually.

Prevention is key for patients at risk for hypothermia and involves educating not only the patients but family members and friends. Patients most at risk are the extremes of age—very young, very old—and people debilitated by trauma, stroke,

diabetes, drug or alcohol intoxication, sepsis, and Raynaud's disease. Mentally ill and disabled patients may acquire hypothermia because they are unaware of the dangers of cold conditions. People without adequate home heating, shelter, diet, or clothing are also at risk. Fatigue, skin colour (dark-skinned patients are more susceptible), malnutrition, hypoxemia, and body piercing can contribute to the risk of frostbite.

Acute Care

Fever. When body temperature is elevated, it is important to initiate interventions to treat fever. The objective of therapy is to increase heat loss, reduce heat production, and prevent complications.

The procedures used to intervene and treat the temperature depend on the cause, any adverse effects, and the strength, intensity, and duration of the elevation. The nurse plays a key role in assessing and implementing temperature-reducing strategies (Box 30-10). The prescribing health care provider may try to determine the cause of the elevated temperature by isolating the causative pyrogen. Necessary culture specimens for laboratory analysis, such as urine, blood, sputum, and tissue from wound sites (see Chapter 32) may need to be obtained. After the cultures have been sent, the prescribing health care provider orders administration of antibiotic medications to destroy pyrogenic bacteria and eliminate the cause of the elevated temperature.

In children, most fevers are caused by viruses, last only briefly, and have limited effects. Children still have immature temperature-control mechanisms so temperatures can rise rapidly. Dehydration and febrile seizures can occur while

temperatures are rising in children between six months and three years of age. Febrile seizures are unusual in children older than five years. The actual temperature, often exceeding 38.8°C, seems to be more important than the rapidity of the temperature increase. Children are at particular risk for fluid volume deficit because they can quickly lose large amounts of fluids in proportion to their body weight. Maintain accurate intake and output records, and encourage fluid consumption.

A fever may also indicate a hypersensitivity response to a medication. Drug fevers can be accompanied by other symptoms of allergy, such as rash or pruritus. Treatment involves withdrawing the particular medication.

Antipyretics are medications that reduce fever. Nonsteroidals such as acetaminophen, salicylates, indomethacin, and ketorolac reduce fever by increasing heat loss. Corticosteroids reduce heat production by interfering with the immune system and can mask signs of infection. Corticosteroids are not used to treat a fever. However, be aware of their effect on suppressing the patient's ability to develop a fever in response to a pyrogen.

Nonpharmacological therapy for fever involves methods that increase heat loss by evaporation, conduction, convection, or radiation. Blankets cooled by circulating water delivered by motorized units increase conductive heat loss. The manufacturer's instructions for applying these hypothermia blankets must be followed because of risk for skin breakdown and "freeze burns." Placing a bath blanket between the patient and the hypothermia blanket and wrapping distal extremities (fingers, toes, and genitalia) are recommended to reduce the risk of injury to the skin and tissue from hypothermia therapy. Traditional methods such as tepid sponge baths, bathing with alcohol water solutions, applying ice packs to axillae and groin areas, and cooling fans should be used cautiously because they lead to shivering. These methods have no demonstrated advantage over antipyretic medications. Nursing measures to enhance body cooling must attempt to avoid stimulating shivering. Shivering is counterproductive and increases energy expenditure up to 400%. Wrapping the patient's extremities has been recommended to reduce the incidence and intensity of shivering.

Heatstroke. Heatstroke is an emergency. Treatment for heatstroke includes moving the patient to a cooler environment; reducing clothing covering body; placing cool, wet towels over skin; and using oscillating fans to increase convective heat loss. Emergency medical treatment may include intravenous fluids and irrigation of the stomach and lower bowel with cool solutions, in addition to cooling blankets.

Hypothermia. The priority of treatment for hypothermia is to prevent a further decrease in body temperature. Removing wet clothes and replacing with dry clothes and wrapping the patient in blankets are key interventions. In health care settings, forced-air warming blankets can actively rewarm hypothermic patients. Away from a health care setting, the patient should be laid under blankets next to a warm person. A conscious patient should drink hot liquids (e.g., soup) and avoid alcohol and caffeine. Keep the patient's head covered, place the patient near a fire or in a warm room, or place heating pads next to areas of the patient's body (head and neck) that lose heat most rapidly.

Restorative and Continuing Care

Educate the patient who has been febrile about the importance of taking and continuing antibiotics as directed until the course

BOX 30-10 Nursing Measures for Patients With a Fever

Assessment

- Obtain core temperature during each phase of a febrile episode.
- Assess for contributing factors such as dehydration, infection, and environmental temperature.
- Identify physiological response to temperature.
- Measure all vital signs.
- Observe skin colour.
- Assess skin temperature.
- Observe for shivering and diaphoresis.
- Assess the patient's comfort and well-being.
- Determine phase of fever: chill, plateau, or fever break.

Interventions (Unless Contraindicated)

- Obtain blood cultures when ordered: Blood specimens are obtained to coincide with temperature spikes when the antigen-producing organism is most pervasive.
- Minimize heat production: Reduce frequency of activities that increase oxygen demand, such as excessive turning in bed; allow rest periods; limit physical activity.
- Maximize heat loss: Reduce external covering on patient's body to promote heat loss through radiation and conduction without inducing shivering; keep clothing and bed linen dry to increase heat loss through conduction and convection.
- Meet requirements for increased metabolic rate: Provide oxygen as ordered to improve oxygen delivery to body cells; provide measures to stimulate appetite; offer well-balanced meals; provide fluids (3 L per day for patient with normal cardiac and renal function) to replace fluids lost through insensible water loss and sweating.
- Promote patient comfort: Encourage the patient to practise oral hygiene for dry oral mucous membranes; control environmental temperature without inducing shivering (between 21°C and 27°C).
- Identify febrile episode phases: Examine previous temperature measurements to identify trends.
- Initiate health teaching as indicated.

of treatment is completed. Children and older adults are at risk for fluid volume deficit because they can quickly lose large amounts of fluids in proportion to their body weight. Encourage intake of preferred fluids.

❖ Evaluation

All nursing interventions are evaluated by comparing the patient's actual response with the expected outcomes of the care plan. This evaluation reveals whether goals of care have been met or whether the plan must be revised. After any intervention, measure the patient's temperature to evaluate for change. Use other evaluative measures such as palpation of the skin and assessment of pulse and respirations. If therapies are effective, body temperature will return to an acceptable range, other vital sign measurements will stabilize, and the patient will report a sense of comfort.

Pulse

The pulse is the bounding of arterial blood flow that is palpable at various points on the body. Blood flows through the body in a continuous circuit. The pulse is an important indicator of the status of the circulatory system.

Physiology and Regulation

Electrical impulses originating from the sinoatrial node travel through heart muscle to stimulate cardiac contraction. Approximately 60 to 70 mL of blood enters the aorta with each ventricular contraction (**stroke volume**). With each stroke volume ejection (blood pushed out of the heart), the walls of the aorta distend, creating a pulse wave that travels rapidly toward the distal ends of the arteries. When a pulse wave reaches a peripheral artery, it can be felt by palpating the artery lightly against underlying bone or muscle. The number of pulsing sensations occurring in one minute is the *pulse rate*.

The volume of blood pumped by the heart during one minute is the **cardiac output**: the product of heart rate and ventricular stroke volume. In an adult, the heart pumps about 5000 mL of blood per minute (e.g., if heart rate is 70 beats per minute and stroke volume is 70 mL, the cardiac output is 4900 mL per minute). A change in heart rate or stroke volume does not always change the heart's output or the amount of blood in the arteries. Mechanical, neural, and chemical factors regulate the strength of heart contractions and its stroke volume. When these factors are unable to alter stroke volume, the heart rate changes to subsequently adjust blood pressure (BP). As heart rate increases, the heart has less time to fill. Without a change in stroke volume, blood pressure decreases. As the heart rate slows, filling time is increased, and blood pressure increases. The inability of blood pressure to respond to increases or decreases in heart rate may indicate a health deviation and must be reported to the prescribing health care provider. An abnormally slow, rapid, or irregular pulse alters cardiac output. It is important to be able to assess the ability of the patient's heart to meet the demands of the body tissues for nutrients by palpating a peripheral pulse or by using a stethoscope to listen to heart sounds (apical rate).

Assessment of Pulse

Any artery can be assessed for pulse rate, but the radial artery is commonly used because it is easily palpated. When a patient's condition suddenly worsens, the carotid artery is the

recommended site for quickly finding a pulse. The heart will continue delivering blood through the carotid artery to the brain as long as possible. When cardiac output declines significantly, peripheral pulses weaken and are difficult to palpate. Nurses most commonly assess the radial and apical pulses in adult patients, but people who are learning to monitor their own heart rates use the radial or carotid pulse (e.g., athletes, patients taking medications for cardiac disease, and patients starting a prescribed exercise regimen). If the **radial pulse** at the wrist is abnormal or intermittent, or if it is inaccessible because of a dressing or cast, assess the apical pulse. When a patient takes medication that affects the heart rate, the apical pulse provides a more accurate assessment of cardiac function. In infants or young children, it is best to assess the brachial or apical pulse because other peripheral pulses are deep and difficult to palpate accurately.

Assessment of other peripheral pulse sites, such as the popliteal or femoral, is unnecessary in routine measurement of vital signs. These alternative peripheral pulses are assessed during a complete physical examination, when surgery or treatment has impaired blood flow to a body part, or when a patient has clinical indications of impaired peripheral blood flow (see Chapter 31). Table 30-2 summarizes pulse sites and criteria for measurement. Skill 30-2 outlines pulse rate assessment. Table 30-3 lists acceptable pulse rate ranges.

Use of a Stethoscope. Use a stethoscope to assess the apical rate (Figure 30-7). The five major parts of the stethoscope are the earpieces, binaurals, tubing, bell chest piece, and diaphragm chest piece.

The plastic or rubber earpieces fit snugly and comfortably in your ears. The binaurals are angled and strong enough so that the earpieces stay firmly in the ears without causing discomfort. To ensure the best reception of sound, the earpieces follow the contour of the ear canal, pointing toward the face when the stethoscope is in place. Stethoscopes can have single or dual tubes. The tubing has thick walls and is flexible yet moderately rigid to eliminate transmission of environmental noise and to prevent the tubing from kinking. Tubing that is longer than 30 to 40 cm decreases the transmission of sound waves, making it more difficult to accurately auscultate sounds.

The chest piece consists of a bell and a diaphragm that are typically rotated from one to the other into position. The diaphragm or bell must be in proper position to hear sounds through the stethoscope. Test the position of the chest piece by tapping lightly on the diaphragm to determine which side is functioning. The diaphragm is the circular, flat portion of the chest piece and is covered by a thin plastic disk. It transmits high-pitched sounds created by the high-velocity movement of air and blood. Lung, heart, and bowel sounds are best auscultated by using the diaphragm. Position the diaphragm to make a tight seal against the patient's skin (Figure 30-8). Exert enough pressure to leave a temporary red ring on the patient's skin when the diaphragm is removed.

The bell is the bowl-shaped chest piece usually surrounded by a rubber ring. The ring avoids chilling the patient with cold metal when the chest piece is placed on the skin. The bell transmits low-pitched sounds created by the low-velocity movement of blood. Heart and vascular sounds are auscultated through the bell. Apply the bell lightly, resting the chest piece on the patient's skin (Figure 30-9). Compressing the bell against the skin reduces low-pitched sound amplification and

Text continued on p. 511

► TABLE 30-2 Pulse Sites

Site (Artery)	Location	Use and Assessment Criteria
Temporal	Over temporal bone of head, above and lateral to eye	Of significance in the diagnosis of temporal arteritis
Carotid	Along medial edge of sternocleidomastoid muscle in neck	During physiological shock or cardiac arrest, when other sites are not palpable
Apical	Fourth to fifth intercostal space at left midclavicular line	Auscultation is performed to obtain apical pulse
Brachial	Groove between biceps and triceps muscles at antecubital fossa	Provides status of circulation to lower arm; to auscultate blood pressure
Radial	Radial or thumb side of forearm at wrist	Common site to assess peripheral pulse and status of circulation to hand
Ulnar	Ulnar side of forearm at wrist	Assess status of circulation to hand; also to perform Allen's test (test for patency of radial artery)
Femoral	Below inguinal ligament, midway between symphysis pubis and anterior superior iliac spine	Appropriate location to assess pulse during physiological shock or cardiac arrest when other pulses are not palpable; to assess status of circulation to leg
Popliteal	Behind knee in popliteal fossa	Assess status of circulation to lower leg
Posterior tibial	Inner side of ankle, below medial malleolus	Assess status of circulation to foot
Dorsalis pedis	Along top of foot, between extension tendons of the great toe and next toe	Assess status of circulation to foot

► SKILL 30-2 Assessing the Radial and Apical Pulses

**Delegation Considerations**

The task of pulse measurement can be delegated to unregulated care providers (UCPs). The nurse is responsible for assessing changes in pulse; therefore, when the task of pulse measurement is delegated, it is important to *inform the unregulated care provider* about the following:

- Patient's history or risk for irregular pulse
- Frequency of pulse measurement in patient
- Patient's usual pulse values
- Abnormalities that should be reported to the health care provider

Equipment

- Stethoscope (for measurement of apical pulse only)
- Watch or clock with second hand or digital display
- Pen and either vital sign flow sheet or documentation record
- Alcohol swab

Procedure**STEPS**

1. Determine need to assess radial or apical pulse.
 - A. Note risk factors for alterations in apical pulse.
 - B. Assess for signs and symptoms of altered stroke volume and cardiac output, such as dyspnea, fatigue, chest pain, orthopnea, syncope, palpitations (unpleasant awareness of heartbeat), jugular venous distension, edema of dependent body parts, and cyanosis or pallor of skin.
2. Assess for factors that normally influence pulse rate and rhythm: age, exercise, position changes, fluid balance, medications, temperature, sympathetic nervous system stimulation.
3. Determine previous baseline apical rate (if available) from patient's record. Otherwise, note baseline radial rate.
4. Explain to patient that pulse or heart rate is to be assessed. If patient was active, wait 5–10 minutes before taking his or her pulse. Encourage patient to relax and not to speak.

RATIONALE

- Use clinical judgement to determine need for assessment.
- Certain conditions heighten risk for pulse alterations (e.g., cardiac disease, cardiac dysrhythmias, sudden chest pain or acute pain from any site, invasive cardiovascular diagnostic tests, surgery, sudden infusion of large volume of intravenous fluid, hemorrhage, administration of medications that alter cardiac function).
- Physical signs and symptoms may indicate alteration in cardiac function.
- These assessments enable you to accurately evaluate the presence and significance of pulse alterations. Acceptable range of pulse rate changes with age (see Table 30-3).
- By comparing rates you can assess for change in patient's condition and evaluate future apical pulse measurements.
- Activity and anxiety elevate heart rate. Patient's voice interferes with your ability to hear sound when you measure apical pulse. Measuring pulse rates at rest allows for objective comparison of values.

Continued

► SKILL 30-2 Assessing the Radial and Apical Pulses—cont'd

5. Perform hand hygiene.
6. If necessary, draw curtain around patient's bed or close room door, or do both.
7. Obtain pulse measurement.
 - A. Radial pulse
 - (1) Assist patient to assume a supine or sitting position.
 - (2) If patient is supine, place patient's forearm straight alongside body, across lower chest, or across upper abdomen with wrist extended straight (see Step 7A[2] illustration). If patient is sitting, bend patient's elbow 90 degrees and support lower arm on chair or on your arm. Slightly flex patient's wrist with palm down (see Step 7A[2] illustration).
 - (3) Place tips of your first two or middle three fingers over groove along radial or thumb side of patient's inner wrist (see Step 7A[3] illustration).

Step 7A(2) Pulse check with patient's forearm at side with wrist extended.

- (4) Lightly compress your fingertips against patient's radius, obliterate pulse initially, and then relax pressure so that pulse becomes easily palpable.
- (5) Determine strength of pulse. Note whether thrust of vessel against your fingertips is bounding (+4), strong (+3), weak (+2), thready (+1), or absent (0).
- (6) After you can feel a regular pulse, look at watch and begin to count pulse rate when second hand reaches a number on watch dial; start counting pulse with "one," then "two," and so on.
- (7) If pulse is regular, count rate for 30 seconds and multiply total by 2.
- (8) If pulse is irregular, count rate for 1 minute (60 seconds). Assess frequency and pattern of irregularity. Compare bilateral radial pulses.

- Hand hygiene reduces transmission of microorganisms between the patient and the nurse.
- These actions maintain patient's privacy, minimize embarrassment, and promote comfort.
- These positions enable easy access to pulse sites.
- Relaxed position of lower arm and slight flexion of wrist promotes exposure of artery to palpation without restriction.
- Fingertips are the most sensitive parts of the hand to palpate arterial pulsation. The thumb has pulsations that may interfere with accuracy.

Step 7A(3) Hand placement for pulse checking radial pulse.

- Pulse is more accurately assessed with moderate pressure. Too much pressure occludes pulse and impairs blood flow.
- Strength reflects volume of blood ejected against arterial wall with each heart contraction. Accurate description of strength improves communication among health care providers, although keep in mind this is subjective data.
- You can determine pulse rate accurately only after you can palpate the pulse. Count of "one" is the first beat palpated after you begin timing.
- A 30-second count is accurate for rapid, slow, or regular pulse rates.
- Inefficient contraction of heart fails to transmit pulse wave, interfering with cardiac output, resulting in irregular pulse. Longer measurement time ensures accurate count.

Critical Decision Point: If pulse is irregular, assess apical or radial pulse to detect a pulse deficit. Count apical pulse rate while a colleague counts radial pulse rate. Begin apical pulse count out loud to simultaneously assess pulses. If pulse count differs by more than two, a pulse deficit exists; this can indicate altered cardiac output.

- B. Apical pulse
 - (1) Perform hand hygiene; clean earpieces and diaphragm of stethoscope with alcohol swab.
 - (2) Draw curtain around patient's bed or close room door, or do both.
 - (3) Assist patient to supine or sitting position. Move aside bed linen and gown to expose sternum and left side of chest.

- These actions reduce transmission of microorganisms between patients and when stethoscopes are shared.
- These actions maintain patient's privacy, minimize embarrassment, and promote comfort.
- Expose portion of patient's chest wall to select auscultatory site.

SKILL 30-2 Assessing the Radial and Apical Pulses—cont'd

video

(4) Locate anatomical landmarks to identify the *point of maximal impulse* (PMI), also called the *apical impulse* (see Steps 7B(4)(a) to 7B(4)(d) illustrations). Heart is located behind and to left of sternum with base at top and apex at bottom. Find angle of Louis just below suprasternal notch between sternal body and manubrium; it can be palpated as a bony prominence (see Step 7B(4)(a) illustration). Slip fingers down each side of angle to find second intercostal space (ICS; see Step 7B(4)(b) illustration). Carefully move fingers down left side of sternum to fifth ICS (see Step 7B(4)(c) illustration) and laterally to the left midclavicular line (MCL; see Step 7B(4)(d) illustration). A light tap felt in an area within 1 to 2 cm of the PMI is reflected from the apex of the heart.

- Use of anatomical landmarks allows correct placement of stethoscope over apex of heart, enhancing ability to hear heart sounds clearly. In a patient with large breasts, ask the patient to move the breast aside so that you can access the PMI site. If you are unable to palpate the PMI, reposition patient on left side. In the presence of severe cardiac disease, the PMI may be located to the left of the MCL or at the sixth ICS.

Step 7B(4)(a) Locating the angle of Louis.

Step 7B(4)(b) Locating the second intercostal space.

Step 7B(4)(c) Locating the fifth intercostal space.

Step 7B(4)(d) Identifying the midclavicular line.

(5) Place diaphragm of stethoscope in palm of your hand for 5 to 10 seconds.

- By warming metal or plastic diaphragm, you avoid startling patient and promote patient's comfort.

Continued

► SKILL 30-2 Assessing the Radial and Apical Pulses—cont'd

- (6) Place diaphragm of stethoscope over PMI at the fifth ICS, at left MCL, and auscultate for normal S_1 and S_2 heart sounds (heard as “lub-dub”; see Step 7B[6] illustrations).

- Allow stethoscope tubing to extend straight without kinks that would distort sound transmission. Normally, S_1 and S_2 heart sounds are high-pitched and best heard with the diaphragm.

Step 7B(6) A, Location of point of maximal impulse (PMI) in adult. B, Stethoscope placement over PMI.

- (7) When S_1 and S_2 are heard with regularity, look at watch and begin to count rate: when second hand reaches a number on watch dial, start counting with “one,” then “two,” and so on.
- (8) If apical rate is regular, count for 30 seconds and multiply by 2.

- You can accurately determine apical rate only after you can auscultate sounds clearly. Count of “one” is first sound auscultated after timing begins.
- Regular apical rate can be assessed within 30 seconds.

Critical Decision Point: If heart rate is irregular or if patient is receiving cardiac medication, count for 1 minute (60 seconds). An irregular rate is more accurately assessed when measured over a longer interval.

- (9) If heart rate is irregular, or patient is receiving cardiovascular medication, count for a full 1 minute (60 seconds), describe pattern of irregularity (S_1 and S_2 occurring early or later after previous sequence of sounds; e.g., every third or every fourth beat is skipped).
- (10) Replace patient's gown and bed linen; assist patient to return to comfortable position.
- (11) Clean earpieces and diaphragm of stethoscope with alcohol swab as necessary.
8. Perform hand hygiene.
 9. Discuss findings with patient as needed.
 10. Compare current readings with previous baseline measurement or acceptable range of heart rate for patient's age (see Table 30-3).
 11. Compare peripheral pulse rate with apical rate, and note any discrepancy.
 12. Compare radial pulse equality between arms, and note any discrepancy.
 13. Correlate pulse rate with data obtained from blood pressure and related signs and symptoms (palpitations, dizziness).
- Regular occurrence of dysrhythmia within 1 minute may indicate inefficient contraction of heart and alteration in cardiac output.
 - These actions restore patient's comfort and promote sense of well-being.
 - Cleaning with an alcohol swab helps control transmission of microorganisms between patients and when the stethoscope is shared.
 - Hand hygiene reduces transmission of microorganisms between patients.
 - Such discussion promotes patient's participation in care and understanding of health status.
 - Evaluate for change in condition and alterations.
 - Differences between measurements indicate pulse deficit and possibly cardiovascular compromise. Abnormalities may necessitate therapy.
 - Differences between radial arteries indicate compromised peripheral vascular system.
 - Pulse rate and blood pressure are interrelated.

► SKILL 30-2 Assessing the Radial and Apical Pulses—cont'd

Unexpected Outcomes

Radial pulse is weak or thready

Apical pulse is greater than 100 beats per minute (tachycardia)

Apical pulse is less than 60 beats per minute (bradycardia)

Related Interventions

- Assess both radial pulses and compare findings. Local obstruction to one extremity (e.g., clot, edema) may decrease peripheral blood flow.
- Perform complete assessment of all pulses (see Chapter 31).
- Observe for symptoms associated with decreased tissue perfusion, such as pallor and cool skin temperature of tissue distal to the weak pulse.
- Measure apical and radial pulse simultaneously to determine presence of pulse deficit.
- Assess for presence of fever, anxiety, pain, recent exercise, hypotension, decreased oxygenation, or dehydration, all of which can elevate pulse.
- Measure all vital signs.
- Assess for factors associated with decreased cardiac output, such as chest pain, dizziness, cyanosis, fatigue, and orthopnea.
- Assess for the presence of factors that may alter heart rate, such as digoxin or other cardiac medications. It may be necessary to withhold prescribed medications until the prescribing health care provider can evaluate the need to adjust dosage.
- Assess for factors associated with decreased cardiac output.

Recording and Reporting

- Record pulse rate with assessment site in nurses' notes or vital signs flow sheet. Document pulse rate in nurses' narrative notes after administration of specific therapies.
- Report abnormal findings to nurse in charge or prescribing health care provider.

Home Care Considerations

- Assess home environment to determine which room will afford quiet environment for auscultating apical rate.

► TABLE 30-3

Acceptable Ranges of Heart Rate

Age	Heart Rate (Beats per Minute)
Infant	120–160
Toddler	90–140
Preschooler	80–110
School-aged child	75–100
Adolescent	60–90
Adult	60–100

Data from Kinney, M. R., Dunbar, S. B., Brooks-Brunn, J., Molter, N., & Vitello-Cicciu, J. M. (1998). *AACN's clinical reference for critical care nursing* (4th ed.). St Louis, MO: Mosby.

creates a “diaphragm of skin.” Some stethoscopes have just one chest piece that combines the features of the bell and diaphragm. With the use of light pressure, the chest piece acts as a bell; with more pressure, it acts as a diaphragm.

The stethoscope is a delicate instrument and requires proper care for optimal function. The earpieces should be removed regularly and cleaned according to the manufacturer's instructions (to remove cerumen). The bell and diaphragm need to be cleaned (to remove dust, lint, and body oils) routinely with alcohol to prevent transmission of microorganisms. The tubing can be cleaned with mild soap and water. Nurses are encouraged to have their own stethoscope. If several nurses use the same stethoscope, the earpieces should be cleansed with an antiseptic prior to each use.

Figure 30-7 Parts of a stethoscope.

Figure 30-8 Positioning the diaphragm of the stethoscope firmly and securely when high-pitched heart sounds are auscultated.

Figure 30-9 Positioning the bell of the stethoscope lightly on the skin to hear low-pitched heart sounds.

Character of the Pulse

Assessment of the radial pulse includes measurement of the rate, rhythm, strength, and bilateral equality. When auscultating an apical pulse, assess rate and rhythm only.

Rate. Before measuring a pulse, review the patient's baseline rate for comparison (see Table 30-3). Some practitioners make baseline measurements of the pulse rate with the patient sitting, standing, and lying. Changes in posture cause changes in pulse rate because of alterations in blood volume and sympathetic nervous system activity. The heart rate temporarily increases when a person changes from a lying to a sitting or standing position.

Always consider the variety of factors influencing the pulse rate (Table 30-4). A single factor or a combination of factors can cause significant changes. If you detect an abnormal rate while you palpate a peripheral pulse, the next step is to assess the apical rate. This requires auscultation of heart sounds, which provides a more accurate assessment of cardiac contraction (see Chapter 31).

Identify the first and second heart sounds (S_1 and S_2). At normal slow rates, S_1 is low-pitched and dull, sounding like a "lub." S_2 is higher-pitched and shorter, creating the sound

► **TABLE 30-4** Factors Influencing Pulse Rates

Factor	Increases Pulse Rate	Decreases Pulse Rate
Exercise	Short-term exercise	Long-term exercise, which conditions the heart and results in a lower resting pulse and a quicker return to resting level after exercise
Temperature	Fever and heat	Hypothermia
Emotions	Anxiety increases sympathetic stimulation, affecting heart rate	Relaxation
Pain	Acute pain, which increases sympathetic stimulation and thereby increases heart rate; the effect of chronic pain on heart rate varies	Unrelieved severe pain, which increases parasympathetic stimulation and thereby affects heart rate
Medications	Positive chronotropic medications such as epinephrine	Negative chronotropic medications such as digitalis, alpha-adrenergic blockers, and calcium channel blockers
Hemorrhage	Loss of blood increases sympathetic stimulation	
Postural changes	Standing or sitting	Lying down
Pulmonary conditions	Diseases causing poor oxygenation, such as asthma and chronic obstructive pulmonary disease (COPD)	

"dub." Each set of "lub-dub" is counted as one heartbeat. Using the diaphragm or bell of the stethoscope, count the number of "lub-dubs" occurring in one minute.

Peripheral and apical pulse rate assessment may reveal variations in heart rate. Two common abnormalities in pulse rate are tachycardia and bradycardia. **Tachycardia** is an abnormally fast heart rate, more than 100 beats per minute in adults. **Bradycardia** is a slow heart rate, less than 60 beats per minute in adults.

An inefficient contraction of the heart that fails to transmit a pulse wave to the peripheral pulse site creates a pulse deficit. Two people are required to detect a **pulse deficit**; one to assess either the radial or apical rate, and the second to simultaneously assess the other rate. Then the two rates are compared.

The difference between the apical and radial pulse rates is the pulse deficit. For example, if the apical rate is 92 beats per minute and the radial rate is 78 beats per minute, the pulse deficit is 14 beats per minute. Pulse deficits are frequently associated with abnormal rhythms.

Rhythm. Normally, a regular interval occurs between each pulse or heartbeat. An interval interrupted by an early or late beat or a missed beat indicates an abnormal rhythm, or **dysrhythmia**. Dysrhythmia threatens the heart's ability to provide adequate cardiac output, particularly if it occurs repetitively. Dysrhythmia is identified by palpating an interruption in successive pulse waves or auscultating an interruption between heart sounds. If dysrhythmia is present, assess the regularity of its occurrence and auscultate the apical rate (see Chapter 31). Dysrhythmias are described as "regularly irregular" or "irregularly irregular."

To document a dysrhythmia, a prescribing health care provider may order electrocardiography, Holter monitoring, or telemetry. In electrocardiography, the electrical activity of the heart is recorded for a 12-second interval. The Holter monitor records 24 hours of electrical activity in a small recorder that the patient wears. In cardiac telemetry, the heart's electrical activity is monitored continuously, and the data are transmitted to a stationary monitor. Telemetry enables observation of heart rhythm during all the patient's daily activities and thus allows for immediate treatment if the rhythm becomes erratic or unstable.

Strength. The strength of a pulse reflects both the volume of blood ejected against the arterial wall with each heart contraction and the condition of the arterial vascular system leading to the pulse site. Normally, the pulse strength remains the same with each heartbeat. Pulse strength may be graded or described as bounding, strong, weak, thready, or absent. It is included during assessment of the vascular system (see Chapter 31).

Equality. Pulses on both sides of the body should be assessed to compare their characteristics. A pulse in one extremity may be unequal to the pulse in the other extremity in strength, or it may be absent in many disease states (e.g., thrombus [clot] formation). All symmetrical pulses can be assessed simultaneously except for the carotid pulses, which should never be measured simultaneously because excessive pressure may occlude blood supply to the brain or trigger carotid reflexes that may result in altered cardiac output.

Nursing Process and Pulse Determination

Pulse assessment helps to determine the general state of cardiovascular health and the body's response to other system imbalances. Tachycardia, bradycardia, and dysrhythmia are defining characteristics of many nursing diagnoses, including the following:

- *Activity intolerance*
- *Anxiety*
- *Decreased cardiac output*
- *Deficient/excess fluid volume*
- *Impaired gas exchange*
- *Hyperthermia*
- *Hypothermia*
- *Acute pain*
- *Ineffective tissue perfusion*

The nursing care plan includes interventions specific for the nursing diagnosis identified and its related factors. For example, the defining characteristics of an abnormal heart rate,

exertional dyspnea, and a patient's verbal report of fatigue lead to a diagnosis of *activity intolerance*. When the related factor is "inactivity after a prolonged illness," interventions focus on increasing the patient's daily exercises. Evaluate patient outcomes by assessing the pulse rate, rhythm, strength, and equality after each intervention.

Respiration

Human survival depends on the ability of oxygen (O_2) to reach body cells and of carbon dioxide (CO_2) to be removed from the cells. **Respiration** is the mechanism that the body uses to exchange gases between the atmosphere and the blood and between the blood and the cells. Respiration involves **ventilation** (the movement of gases in and out of the lungs), **diffusion** (the movement of oxygen and carbon dioxide between the alveoli and the red blood cells), and **perfusion** (the distribution of red blood cells to and from the pulmonary capillaries). To analyze respiratory efficiency, assessment data must be integrated from all three processes. Ventilation is assessed by determining respiratory rate, respiratory depth, and respiratory rhythm. Diffusion and perfusion are assessed by determining oxygen saturation.

Physiological Control

Breathing is generally a passive process; a person thinks little about it. The respiratory centre in the brain stem regulates the involuntary control of respirations. Adults normally breathe in a smooth, uninterrupted pattern, 12 to 20 times a minute.

Ventilation is regulated by levels of carbon dioxide, oxygen, and hydrogen ion concentration (pH) in the arterial blood. The most important factor is the level of CO_2 in the arterial blood. An elevation in the CO_2 level causes the respiratory control system in the brain to increase the rate and depth of breathing. The increased ventilatory effort removes excess CO_2 (which is the state of hypercarbia) by increasing exhalation. However, patients with chronic lung disease have ongoing hypercarbia. For them, chemoreceptors in the carotid artery and aorta become sensitive to **hypoxemia**, or low levels of arterial O_2 . If arterial O_2 levels fall, these receptors signal the brain to increase the rate and depth of ventilation. Hypoxemia helps control ventilation in patients with chronic lung disease. Because low levels of arterial O_2 provide the stimulus that allows the patient to breathe, administration of high oxygen levels can be dangerous for these patients.

Mechanics of Breathing

Although breathing is normally passive, muscular work is involved in moving the lungs and chest wall. Inspiration is an active process. During inspiration, the respiratory centre sends impulses along the phrenic nerve, causing the diaphragm to contract. Abdominal organs move downward and forward, increasing the length of the chest cavity to move air into the lungs. The diaphragm moves approximately 1 cm, and the ribs retract upward from the body's midline approximately 1.2 to 2.5 cm. During a normal, relaxed breath, a person inhales 500 mL of air. This amount is referred to as the **tidal volume**. During expiration, the diaphragm relaxes and the abdominal organs return to their original positions. The lung and chest wall return to a relaxed position (Figure 30-10). In contrast to inhalation, expiration is a passive process. The normal rate and depth of ventilation, **eupnea**, is interrupted by sighing. The sigh, a prolonged deeper breath, is a protective physiological

Figure 30-10 Illustration of diaphragmatic and chest wall movement during inspiration and expiration.

mechanism for expanding small airways and alveoli not ventilated during a normal breath.

The accurate assessment of respiration depends on the recognition of normal thoracic and abdominal movements. During quiet breathing, the chest wall gently rises and falls. Contraction of the accessory muscles of breathing (i.e., the intercostal muscles between the ribs and the muscles in the neck and shoulders) is not visible. During normal quiet breathing, diaphragmatic movement causes the abdominal cavity to rise and fall slowly.

Assessment of Ventilation

Special equipment is not needed to measure respirations, but measurement must not be haphazard. Accurate measurement requires observation and palpation of chest wall movement.

A sudden change in the character of respirations is important. Because respiration is tied to the function of numerous body systems, consider all variables when changes occur (Box 30-11). For example, abdominal trauma may injure the phrenic nerve, which is responsible for diaphragmatic contraction. The extent of the injury and the implications for the respiratory system are important to understand.

Try to not let the patient know that you are assessing his or her respiration. A patient aware of your intentions may consciously alter the rate and depth of breathing. The best time to measure respiration is immediately after measuring the pulse while your hand remains on the patient's wrist as it rests over the chest or abdomen. When assessing, keep in mind the patient's usual ventilatory rate and pattern, the influence any disease or illness has on respiratory function, the relationship between respiratory and cardiovascular function, and the influence of therapies on respiration. The objective measurements in assessing respiratory status include the rate and depth of breathing and the rhythm of ventilatory movements (Skill 30-3).

Respiratory Rate. Observe both inspiration and expiration when counting ventilation or respiration rate. The respiratory rate varies with age (Table 30-5) and usually decreases with age.

An apnea monitor is a respiratory monitoring device that aids in respiratory assessment. Leads that sense movement are attached to the patient's chest wall. Absence of chest wall movement triggers the apnea alarm. Apnea monitoring is used

BOX 30-11

Factors Influencing Character of Respiration

Exercise

Exercise increases respiratory rate and depth to meet body's need for additional O_2 and to rid body of CO_2 .

Acute Pain

Pain alters rate and rhythm of respiration; breathing becomes shallow.

Patient inhibits or splints chest wall movement when pain is in area of chest or abdomen.

Anxiety

Anxiety increases respiratory rate and depth as a result of sympathetic stimulation.

Smoking

Chronic smoking changes pulmonary airways, resulting in increased rate of respirations at rest when the person is not smoking.

Body Position

A straight, erect posture promotes full chest expansion.

A stooped or slumped position impairs ventilatory movement.

Lying flat prevents full chest expansion.

Medications

Opioids, general anaesthetics, and sedative hypnotics depress respiratory rate and depth.

Amphetamines and cocaine may increase respiratory rate and depth.

Bronchodilators slow respiratory rate by causing airway dilation.

Neurological Injury

Injury to the brain stem impairs the respiratory centre and inhibits respiratory rate and rhythm.

Hemoglobin Function

In the state of anemia, decreased hemoglobin levels reduce O_2 -carrying capacity of the blood, which results in increases in respiratory rate.

Increased altitude lowers the amount of saturated hemoglobin, which increases respiratory rate and depth.

Abnormalities in blood cell function (e.g., sickle cell disease) reduce ability of red blood cells to carry oxygen, which results in increases in respiratory rate and depth.

TABLE 30-5

Acceptable Ranges of Respiratory Rates by Age

Age	Rate (Breaths per Minute)
Newborn	30–60
Infant (6 months)	30–50
Toddler (2 years)	25–32
Child and preadolescent (3–12 years)	20–30
Adolescent (13–18 years)	16–19
Adult (older than 18 years)	12–20

frequently with infants in hospitals and at home to observe for prolonged apneic events.

Ventilatory Depth. Depth of respiration is assessed by observing the degree of excursion or movement in the patient's chest wall. Ventilatory movements can be described as "deep,"

► SKILL 30-3 Assessing Respirations

Delegation Considerations

The task of measuring respiration can be delegated to unregulated care providers (UCPs). The nurse is responsible for assessing for change in respiration rate, rhythm, and depth; therefore, when the task of measuring respiration is delegated, it is important to *inform the unregulated care provider* about the following:

- The patient's history or risk for abnormal respiratory status
- The frequency of respiration measurement for a specific patient
- Abnormalities that should be reported to the health care provider

Procedure

STEPS

1. Determine need to assess patient's respiration:
 - A. Note presence of risk factors for respiratory alterations.
 - B. Assess for signs and symptoms of respiratory alterations, such as bluish (cyanotic) appearance of nail beds, lips, mucous membranes, and skin; restlessness, irritability, confusion, and reduced level of consciousness; pain during inspiration; laboured or difficult breathing; adventitious breath sounds (see Chapter 31), inability to breathe spontaneously; thick, frothy, blood-tinged, or copious sputum produced on coughing.
2. Assess pertinent laboratory values.
 - A. **Arterial blood gases** (normal values may vary slightly between institutions):
 pH: 7.35–7.45 mm Hg
 PaCO₂: 35–45 mm Hg
 PaO₂: 80–100 mm Hg
 SaO₂: 95%–100%
 - B. **Pulse oximetry (SpO₂)**: Normal levels are 92%–100%; 85%–89% may be acceptable for certain chronic disease conditions; less than 85% is abnormal (see Skill 30-4).
 - C. **Specific tests of the complete blood cell count (CBC)**: (normal values for adults may vary between institutions and references consulted):
 Hemoglobin: 135–180 g/L in male patients; 120–160 g/L in female patients
 Hematocrit: 0.43–0.49 in male patients; 0.38–0.44 in female patients
 Red blood cell count: $4.7\text{--}5.74 \times 10^{12}/\text{L}$ in male patients; $4.2\text{--}4.87 \times 10^{12}/\text{L}$ in female patients
3. Determine previous baseline respiratory rate (if available) from patient's record.
4. Perform hand hygiene.
5. Draw curtain around patient's bed or close room door, or do both.

Equipment

- Watch with second hand or digital display
- Pen and either vital sign flow sheet or record form

RATIONALE

- You use clinical judgement to determine need for assessment.
- Conditions that heighten risk for alterations in ventilation—detected by changes in respiratory rate, depth, and rhythm—include fever, pain, anxiety, diseases of chest muscles, constrictive chest or abdominal dressings, gastric distension, chronic pulmonary diseases, traumatic chest injury, presence of a chest tube, respiratory infection, pulmonary edema and emboli, anemia, and head injury with damage to brain stem.
- Physical signs and symptoms indicate alterations in respiratory status related to ventilation.
- Arterial blood gases measure arterial blood pH partial pressure of O₂ (PaO₂) and CO₂ (PaCO₂), and arterial O₂ saturation (SaO₂), which reflects patient's oxygenation status.
- Although 95% is considered normal, 90% can be considered acceptable in patients with disorders such as sleep apnea. SpO₂ less than 85% is often accompanied by changes in respiratory rate, depth, and rhythm.
- Hemoglobin, hematocrit, and red blood cell count (three of several CBC tests) measure the concentration of hemoglobin volume of red blood cells, and red blood cell count, all of which reflect patient's capacity to carry O₂.
- Enables the ability to assess for changes in patient's condition and provides comparison with future respiratory measurements.
- Hand hygiene prevents transmission of microorganisms between the patient and the nurse.
- Drawing the curtain and closing the room door maintains patient's privacy, minimizes embarrassment, and promotes comfort.

Critical Decision Point: Patients with difficulty breathing (dyspnea), such as those with congestive heart failure, with abdominal ascites, or in late stages of pregnancy, should be assessed in the position of greatest comfort. Repositioning may increase the work of breathing, which increases respiratory rate.

6. Ensure patient is in comfortable position, preferably sitting or lying with the head of the bed elevated 45 to 60 degrees. Move bed linen or gown to be sure patient's chest is visible.
- Sitting erect promotes full ventilatory movement. A clear view of the chest wall and abdominal movements is needed for assessment.

Continued

> SKILL 30-3 Assessing Respirations—cont'd

7. Place patient's arm in relaxed position across his or her abdomen or lower chest, or place your hand directly over patient's upper abdomen (see Step 7 illustration).
- A similar position used during pulse assessment allows you to assess respiratory rate inconspicuously. Patient's hand or your hand rises and falls during respiratory cycle.

Step 7 Nurse's hand over patient's abdomen to check respiration.

8. Observe complete respiratory cycle (one inspiration and one expiration).
 9. After observing cycle, look at watch's second hand. When second hand reaches a number on watch dial, begin counting respiratory cycles, starting with "one" for the first full cycle, then "two," and so on.
 10. If rhythm is regular, count number of respiratory cycles in 30 seconds and multiply by 2. If rhythm is irregular, slower than 12 per minute, or faster than 20 per minute, count for 1 full minute.
 11. Note depth of respirations, which you subjectively assess by observing degree of chest wall movement while counting respiratory rate. You can also objectively assess respiratory depth by palpating patient's chest wall excursion or auscultating the posterior thorax after respiratory rate has been counted (see Chapter 31). Depth is described as "shallow," "normal," or "deep."
 12. Note rhythm of ventilatory cycle. Normal breathing is regular and uninterrupted. Sighing should not be confused with abnormal rhythm.
- You can determine rate accurately only after you have viewed patient's respiratory cycle.
 - Timing begins with count of one. Respirations occur more slowly than pulse.
 - Respiratory rate is equivalent to number of respiratory cycles per minute. Suspected irregularities necessitate assessment for at least 1 minute.
 - Character of ventilatory movement may reveal specific disease state restricting volume of air from moving into and out of the lungs.
 - Character of ventilations can reveal specific types of alterations. Without being aware of it, people periodically take single deep breaths or sighs to expand small airways prone to collapse.

Critical Decision Point: Any irregular respiratory pattern or period of apnea (the cessation of respiration for several seconds) in an adult is a symptom of underlying disease and must be reported to the prescribing health care provider or nurse in charge. Further assessment may be required (see Chapter 31), and immediate intervention may be needed. An irregular respiratory rate and short apneic spells are normal only in newborns.

13. Move back bed linen and patient's gown.
 14. Perform hand hygiene.
 15. Discuss findings with patient as needed.
 16. If patient's respiration is assessed for the first time, document rate, rhythm, and depth as baseline values.
 17. Compare respiration data with patient's previous baseline values and with normal values for rate, rhythm, and depth.
- This action restores patient's comfort and promotes sense of well-being.
 - Hand hygiene reduces transmission of microorganisms between patients.
 - Such discussion promotes patient's participation in care and understanding of health status.
 - These data are used for comparing data from future respiratory assessments.
 - These data allow you to assess for changes in patient's condition and for presence of respiratory alterations.

Unexpected Outcomes

Patient's respiratory rate is less than 12 (bradypnea) or more than 20 (tachypnea) breaths per minute, depth is increased or decreased, rhythm is irregular, or patient feels "short of breath"

Related Interventions

- Observe for related factors, including obstructed airway, abnormal breath sounds, productive cough, restlessness, irritability, anxiety, and confusion.
- Position patient in a supported sitting position (semi-Fowler's or high Fowler's), unless contraindicated.
- Provide oxygen as ordered.
- When possible, remove respiratory irritants from the environment, such as second-hand smoke and perfumes.

► SKILL 30-3 Assessing Respirations—cont'd

Recording and Reporting

- Record respiratory rate and character in nurses' notes or vital sign flow sheet. Indicate type and amount of oxygen therapy if it was used by the patient during assessment. Document respiratory rate in nurses' narrative notes after administration of specific therapies.
- Report abnormal findings to nurse in charge or to prescribing health care provider.

Home Care Considerations

- Assess for environmental factors in the home that may influence patient's respiration, such as second-hand smoke, poor ventilation, or gas fumes.

► TABLE 30-6 Alterations in Breathing Pattern

Alteration	Description
Bradypnea	Rate of breathing is regular but abnormally slow (<12 breaths per minute).
Tachypnea	Rate of breathing is regular but abnormally rapid (>20 breaths per minute).
Hyperpnea	Respirations are laboured, increased in depth, and increased in rate (>20 breaths per minute). This occurs normally during exercise.
Apnea	Respirations cease for several seconds and then resume. Persistent cessation results in respiratory arrest.
Hyperventilation	Rate and depth of respirations increase. Hypocarbica may occur.
Hypoventilation	Respiratory rate is abnormally low, and depth of ventilation may be depressed. Hypercarbica may occur.
Cheyne-Stokes respiration	Respiratory rate and depth are irregular, characterized by alternating periods of apnea and hyperventilation. Respiratory cycle begins with slow, shallow breaths that gradually increase to abnormal rate and depth. The pattern reverses, breathing slows and becomes shallow, climaxing in apnea before respiration resumes.
Kussmaul's respiration	Respirations are abnormally deep, regular, and increased in rate.
Biot's respiration	Respirations are abnormally shallow for two to three breaths, followed by irregular period of apnea.

“normal,” or “shallow.” A deep respiration involves full expansion of the lungs with full exhalation. Respirations are shallow when only a small quantity of air passes through the lungs and ventilatory movement is difficult to see. Objective techniques are used if chest excursion is unusually shallow (see Chapter 31). Table 30-6 summarizes breathing pattern alterations.

Ventilatory Rhythm. Breathing pattern can be determined by observing the chest or the abdomen. Diaphragmatic breathing results from the contraction and relaxation of the diaphragm and is best observed by watching abdominal movements. Healthy men and children usually demonstrate diaphragmatic breathing. Women tend to use thoracic muscles to breathe; therefore, movements are best observed in the upper chest. Laboured respirations involve use of the accessory muscles of respiration visible in the neck. When a foreign body interferes with the movement of air in and out of the lungs, the intercostal spaces in the rib cage retract during inspiration, indicating increased respiratory effort. A longer

expiration phase is evident when the outward flow of air is obstructed (e.g., as in asthma). In infants, additional indicators of respiratory distress are nasal flaring, grunting, and wheezing, making it important to look, listen, and feel when assessing breathing patterns in this population.

With normal breathing, a regular interval occurs after each respiratory cycle. Infants tend to breathe less regularly. The young child may breathe slowly for a few seconds and then suddenly breathe more rapidly. Estimate the time interval after each respiratory cycle. Respiration is regular or irregular in rhythm.

Assessment of Diffusion and Perfusion

To evaluate the respiratory processes of diffusion and perfusion, the oxygen saturation of the blood is measured. Blood flow through the pulmonary capillaries contains red blood cells for oxygen attachment. After oxygen diffuses from the alveoli into the pulmonary blood, most of the oxygen attaches to hemoglobin molecules in red blood cells. The red blood cells then carry the oxygenated hemoglobin molecules through the left side of the heart and out to the peripheral capillaries, where the oxygen detaches, depending on the needs of the tissues.

The percentage of hemoglobin that is bound with oxygen in the arteries is the percentage of saturation of hemoglobin (SaO₂). This value is usually between 95 and 100%. SaO₂ is affected by factors that interfere with ventilation, perfusion, or diffusion (see Chapter 38). The saturation of venous blood (SvO₂) is lower because the tissues have removed some of the oxygen from the hemoglobin molecules. A normal value for SvO₂ is 70%. SvO₂ is affected by factors that interfere with or increase the tissue's need for oxygen.

Measurement of Arterial Oxygen Saturation. A pulse oximeter permits the indirect measurement of oxygen saturation (Skill 30-4). This device contains a probe with a light-emitting diode (LED) and photo detector connected by cable to an oximeter (Figures 30-11 and 30-12). The LED emits light wavelengths that are absorbed differently by oxygenated and deoxygenated hemoglobin molecules. The photo detector detects the amount of oxygen bound to hemoglobin molecules; the oximeter calculates the pulse saturation (SpO₂).

The photo detector is in the oximeter probe. Select the appropriate probe to reduce measurement error. Digit probes are spring-loaded and conform to various sizes. Earlobe probes have greater accuracy at lower saturations and are least affected by peripheral vasoconstriction. Disposable sensor pads can be applied to a variety of sites, even the bridge of an adult's nose or the sole of an infant's foot. Factors that affect light transmission or peripheral arterial pulsations also affect the ability of the photo detector to measure SpO₂ (Box 30-12). Control of these factors allows accurate interpretation of abnormal SpO₂ measurements.

► SKILL 30-4 Measuring Oxygen Saturation (Pulse Oximetry)

video

Delegation Considerations

The task of measuring oxygen saturation can be delegated to unregulated care providers (UCPs). The nurse is responsible for assessing the effect of changes in oxygen saturation; therefore, when the task of measuring oxygen saturation is delegated, it is important to *inform the unregulated care provider* about the following:

- The importance of notifying the nurse immediately of any reading lower than SpO₂ of 90%
- How to select appropriate sensor site and probe for measurement of oxygen saturation
- The frequency of oxygen saturation measurements for the patient
- Factors that can falsely lower SpO₂ (see Box 30-12)

Procedure

STEPS

1. Determine need to measure patient's oxygen saturation:
 - A. Note risk factors, including acute or chronic compromised respiratory function; recovery from general anesthesia or monitored sedation; traumatic injury to chest; ventilator dependence; activity intolerance; and changes in supplemental oxygen therapy.
 - B. Assess for signs and symptoms such as altered respiratory rate, depth, or rhythm; adventitious breath sounds (see Chapter 31); cyanotic appearance of nail beds, lips, mucous membranes, and skin; restlessness, irritability, or confusion; reduced level of consciousness; and laboured or difficult breathing.
2. Assess for factors that normally influence measurement of SpO₂ (see Box 30-12), such as oxygen therapy, hemoglobin level, temperature, and medications (e.g., bronchodilators).
3. Review patient's medical record for pulse oximetry order, or consult agency policy or procedure manual for standard of care for measurement.
4. Determine site most appropriate for sensor probe placement (e.g., digit, earlobe) by assessing capillary refill (see Chapter 31) and skin condition. If capillary refill is less than 3 seconds, choose another site.
 - A. Site needs to have adequate circulation and be free of moisture.
 - B. If peripheral digit is selected, it must be free of polish or artificial nail.
 - C. If tremors are present, use earlobe as site.
 - D. If patient is obese, clip-on probe may not fit; obtain a single-use tape-on probe.
5. Determine previous baseline SpO₂ (if available) from patient's record.
6. Explain purpose of procedure to patient and how oxygen saturation will be measured.
7. Perform hand hygiene.
8. Position patient comfortably. If finger is chosen as monitoring site, support patient's lower arm.
9. Use acetone to remove any fingernail polish from digit to be assessed.

Equipment

- Oximeter
- Oximeter probe appropriate for patient and recommended by manufacturer
- Acetone or nail polish remover, if needed
- Pen and either vital sign flow sheet or documentation form

RATIONALE

- Clinical judgement is used to determine need for assessment.
- Certain conditions heighten risk for decreased oxygen saturation.
- Physical signs and symptoms may be indicative of abnormal oxygen saturation.
- This assessment enables you to accurately assess oxygen saturation variations. Peripheral vasoconstriction related to hypothermia can interfere with SpO₂ determination.
- Medical order may be needed to assess oxygen saturation.
- Sensor requires pulsating vascular bed to identify hemoglobin molecules that absorb emitted light. Changes in SpO₂ are reflected in the circulation of the finger capillary bed within 30 seconds and the capillary bed of earlobe within 5–10 seconds. Moisture prevents the sensor from detecting SpO₂ levels. Artificial nails and nail polish colours alter readings. Motion artifact is the most common cause of a false reading.
- Nail polish interferes with accuracy of readings. Opaque coatings decrease light transmission; nail polish containing blue pigment can absorb light emissions and falsely alter saturation measurement.
- Baseline information provides basis for comparison and assists in assessment of current status and evaluation of interventions.
- Explaining procedures promotes patient's cooperation and increases compliance.
- Hand hygiene reduces transmission of microorganisms between the patient and the nurse.
- This positioning enables probe positioning and decreases motion artifact that interferes with SpO₂ determination.
- Nail polish can interfere with accuracy of readings. Opaque coatings decrease light transmission; polish containing blue pigment can absorb light emissions and falsely alter oximetry measurements.

SKILL 30-4 Measuring Oxygen Saturation (Pulse Oximetry)—cont'd

10. Instruct patient to breathe normally.
 11. Attach sensor probe to monitoring site. Inform patient that clip-on probe feels like a clothespin on the finger but will not hurt.
- Normal breathing prevents large fluctuations in respiratory rate and depth and prevents possible errors in SpO₂ reading.
 - To avoid startling patient, prepare patient to feel pressure of sensor probe's spring tension on a peripheral digit or earlobe.

Critical Decision Point: Do not attach probe to finger, ear, or bridge of nose if area is edematous or skin integrity is compromised. Do not attach probe to hypothermic fingers. Select ear or bridge of nose if adult patient has history of peripheral vascular disease. Do not use sensors on earlobe and bridge of nose in infants and toddlers because of skin fragility. Do not use disposable adhesive probes if patient has latex allergy. Do not place probe on same extremity as electronic blood pressure cuff because blood flow to finger is temporarily interrupted when cuff inflates; this results in inaccurate readings that trigger alarms.

12. Once sensor is in place, turn on oximeter. Observe pulse waveform and intensity display, and listen for audible beep. Correlate oximeter pulse rate with patient's radial pulse. Oximeter pulse rate and patient's radial pulse should be the same. If differences are present, re-evaluate oximeter probe placement, and reassess pulse rates.
 13. Leave probe in place until oximeter readout reaches constant value and pulse display reaches full strength during each cardiac cycle. Inform patient that oximeter alarm will sound if probe falls off or if patient moves probe. Read SpO₂ on digital display.
 14. If SpO₂ monitoring is to be continuous, verify SpO₂ alarm limits and alarm volume, which are preset by the manufacturer at a minimum of 85% and a maximum of 100%. Determine limits for SpO₂ and pulse rate alarms on the basis of each patient's condition. Verify that alarms are functional. Assess skin integrity under sensor probe every two hours. Relocate sensor probe at least every 4 hours and more frequently if skin integrity is altered or tissue perfusion compromised.
 15. Assist patient to return to comfortable position.
 16. Perform hand hygiene.
 17. Discuss findings with patient as needed.
 18. If SpO₂ measurements are intermittent or spot-checked, remove probe and turn oximeter power off between measurements. Store probe in appropriate location.
 19. Compare SpO₂ readings with patient's baseline and acceptable values.
 20. Correlate SpO₂ with SaO₂ obtained from arterial blood gas measurements (see Chapter 39) if available.
 21. Correlate SpO₂ reading with data obtained from assessment of respiratory rate, depth, and rhythm (see Skill 30-3).
- Pulse waveform and intensity display enables detection of valid pulse to SpO₂ value. Double-checking pulse rate ensures oximeter accuracy.
 - Reading takes 10 to 30 seconds, depending on site selected.
 - Alarms must be set at appropriate limits and volumes to avoid frightening patients and visitors.
 - Spring tension of sensor probe or sensitivity to disposable sensor probe adhesive can cause skin irritation and lead to disruption of skin integrity.
 - This action restores patient's comfort and promotes sense of well-being.
 - Hand hygiene reduces transmission of microorganisms between the patient and the nurse.
 - Such discussion promotes patient's participation in care and understanding of health status.
 - Batteries will be depleted if oximeter is left on. Sensor probes are expensive and vulnerable to damage.
 - Comparison reveals presence of abnormality.
 - Reliability of noninvasive assessments is documented.
 - Measurements of ventilation, perfusion, and diffusion are interrelated.

Unexpected Outcomes

SpO₂ is less than 90%

Pulse rate indicated on oximeter is lower than patient's radial or apical pulse

Related Interventions

- Verify that oximeter probe is intact and that outside light transmission does not influence measurement.
- Observe for signs associated with decreased oxygenation (e.g., anxiety, restlessness, tachycardia, cyanosis).
- Verify that supplemental oxygen delivery system is delivered as ordered and is functioning properly.
- Minimize factors that alter SpO₂ (e.g., lung secretions, increased activity, hyperthermia).
- Position patient to promote optimal ventilation (e.g., high Fowler's position for obese patient).
- Reposition sensor probe to alternative site with increased blood flow.
- Assess patient for signs of altered cardiac output (e.g., decreased blood pressure, cool skin, confusion).

Continued

► SKILL 30-4 Measuring Oxygen Saturation (Pulse Oximetry)—cont'd

video

Recording and Reporting

- Record SpO₂ value on nurses' notes or vital sign flow sheet, indicating type and amount of oxygen therapy used by patient during assessment. Record any signs and symptoms of oxygen desaturation in nurses' narrative notes. Report abnormal findings to nurse in charge or prescribing health care provider.
- Document SpO₂ in nurses' narrative notes after administration of specific therapies.
- Record in nurses' notes patient's use of continuous or intermittent pulse oximetry.

Home Care Considerations

- Pulse oximetry is used in home care to noninvasively monitor oxygen therapy or changes in oxygen therapy.
- Instruct caregivers to examine oximeter site before applying sensor.
- Instruct caregivers on procedure to implement when oxygen saturation not within acceptable values.

Figure 30-12 Spring tension oximeter probe **Source:** Forbes, C. D. & Jackson, W. F. (2003). *Color atlas and text of clinical medicine* (3rd ed., p. 153, Fig. 4.22). Edinburgh: Mosby.

Nursing Process and Respiratory Vital Signs

Measurements of respiratory rate, pattern, and depth, along with SpO₂, enable the assessment of ventilation, diffusion, and perfusion. Other assessments also involve respiratory status (see Chapter 31). Each measurement provides clues in determining the nature of a patient's problem. Respiratory

► BOX 30-12 Factors Affecting Determination of Pulse Oxygen Saturation (SpO₂)

Interference with Light Transmission

Outside light sources interfere with oximeter's ability to process reflected light.

Carbon monoxide (caused by smoke inhalation or poisoning) artificially elevates SpO₂ by absorbing light in a similar way that oxygen does.

Patient motion interferes with oximeter's ability to process reflected light.

Jaundice interferes with oximeter's ability to process reflected light.

Intravascular dyes (e.g., methylene blue) absorb light in a similar way that deoxyhemoglobin does and artificially lower saturation.

Nail polish, artificial nails, and metal studs in nails interfere with light absorption and the ability of the oximeter to process reflected light.

Dark skin pigment sometimes results in signal loss or overestimation of saturation.

Reduction of Arterial Pulsations

Peripheral vascular disease (atherosclerosis) reduces pulse volume.

Hypothermia at assessment site decreases peripheral blood flow.

Pharmacological vasoconstrictors (epinephrine, dopamine) decrease peripheral pulse volume.

Low cardiac output and hypotension decrease blood flow to peripheral arteries.

Peripheral edema obscures arterial pulsation.

Tight probe records venous pulsations in the finger that compete with arterial pulsations.

assessment data are defining characteristics of many nursing diagnoses, including the following:

- *Activity intolerance*
- *Ineffective airway clearance*
- *Anxiety*
- *Ineffective breathing pattern*
- *Impaired gas exchange*
- *Acute pain*
- *Ineffective tissue perfusion*
- *Dysfunctional ventilatory weaning response*

The nursing care plan includes interventions specific for the nursing diagnosis identified and the related factors. For example, the defining characteristics of tachypnea, changes in depth of respirations, use of accessory muscles, cyanosis, and a decline in SpO₂ lead to a diagnosis of *impaired gas exchange*. Related factors may include lung surgery, history of chronic

obstructive lung disease, and history of heavy smoking. Evaluate patient outcomes by assessing the respiratory rate, ventilatory depth, rhythm, and SpO₂ after each intervention.

Blood Pressure

Blood pressure is the force exerted on the walls of an artery by the pulsing blood under pressure from the heart. Blood flows throughout the circulatory system because of pressure changes. It moves from an area of high pressure to an area of low pressure. Systemic or arterial blood pressure (the blood pressure in the system of arteries in the body) is a good indicator of cardiovascular health. The heart's contraction forces blood under high pressure into the aorta. The peak of maximum pressure when ejection occurs is the **systolic** blood pressure. When the ventricles relax, the blood remaining in the arteries exerts **diastolic** blood pressure, which is the minimal pressure exerted against the arterial walls at any time.

The standard unit for measuring blood pressure is millimetres of mercury (mm Hg). The measurement indicates the height to which the blood pressure can raise a column of mercury. It is recorded as the systolic reading over the diastolic reading (e.g., 120/80). The difference between systolic and diastolic pressure is the **pulse pressure**. For a blood pressure of 120/80, the pulse pressure is 40. This parameter has been recently considered as a potential indicator of cardiovascular disease, given its relationship to compliance or stiffening of the arteries.

Physiology of Arterial Blood Pressure

Blood pressure reflects the interrelationships of cardiac output, peripheral vascular resistance, blood volume, blood viscosity, and artery elasticity. Knowledge of these hemodynamic variables helps in the assessment of blood pressure alterations.

Cardiac Output. Blood pressure depends on cardiac output. When volume increases in an enclosed space, such as a blood vessel, the pressure in that space rises. As cardiac output increases, more blood is pumped against arterial walls, causing the blood pressure to rise. Cardiac output increases as a result of an increase in heart rate, greater heart muscle contractility, or an increase in blood volume. Changes in heart rate can occur faster than changes in heart muscle contractility or blood volume. A rapid or significant increase in heart rate decreases the heart's ability to fill, resulting in blood pressure decreasing.

Peripheral Resistance. Blood pressure depends on peripheral vascular resistance. Blood circulates through a network of arteries, arterioles, capillaries, venules, and veins. Arteries and arterioles are surrounded by smooth muscle that contracts or relaxes to change the size of the lumen. Normally, arteries and arterioles remain partially constricted to maintain a constant flow of blood. The size of arteries and arterioles changes to adjust blood flow to the needs of local tissues. For example, when a major organ requires more blood, the peripheral arteries constrict, decreasing their supply of blood. More blood then becomes available to the major organ because of the resistance change in the periphery. Peripheral vascular resistance is the resistance to blood flow determined by the tone of the vascular musculature and diameter of blood vessels. The smaller the lumen of a vessel, the greater the resistance to blood flow. As resistance rises, arterial blood pressure rises. As vessels dilate and resistance falls, blood pressure subsequently decreases.

Blood Volume. The volume of blood circulating within the vascular system affects blood pressure. Most adults have a circulating blood volume of approximately 5000 mL. Normally, this blood volume remains constant. However, if volume increases, more pressure is exerted against arterial walls. For example, the rapid, uncontrolled infusion of intravenous fluids would typically increase blood pressure. When circulating blood volume decreases, as with hemorrhage or dehydration, blood pressure would subsequently decrease.

Viscosity. The thickness or viscosity of blood affects the ease with which blood flows through the small vessels. The **hematocrit**, or percentage of red blood cells in the blood, determines blood viscosity. When the hematocrit rises and blood flow slows, the heart must contract more forcefully to move the viscous blood through the circulatory system. This results in arterial blood pressure increasing.

Elasticity. Normally, the walls of an artery are elastic and easily distensible. As pressure within the arteries increases, the diameter of the vessel walls increases to accommodate the rising pressure change. Arterial distensibility prevents wide fluctuations in blood pressure. However, in certain diseases, such as arteriosclerosis, vessel walls lose their elasticity and are replaced by fibrous tissue that cannot stretch as well. With reduced elasticity, resistance to blood flow is greater. As a result, when the left ventricle ejects its stroke volume, the vessels no longer yield to pressure. Instead, a given volume of blood is forced through the rigid arterial walls, and systemic pressure rises. Systolic pressure is more significantly elevated than diastolic pressure as a result of reduced arterial elasticity.

Most importantly, each hemodynamic factor significantly affects the others. For example, as arterial elasticity declines, peripheral vascular resistance increases. The complex control of the cardiovascular system normally prevents any single factor from permanently changing the blood pressure. For example, if the blood volume falls, the body compensates with increased vascular resistance.

Factors Influencing Blood Pressure

Blood pressure is not constant; it is continually influenced by many factors. One measurement cannot adequately reflect a patient's blood pressure. Blood pressure changes from heart-beat to heartbeat. Blood pressure trends, not individual measurements, guide nursing interventions. By understanding these factors, you can more accurately interpret blood pressure readings.

Age. Normal blood pressure levels vary throughout life. Blood pressure increases during childhood. The level of a child's or adolescent's blood pressure is assessed with regard to body size and age. An infant's systolic blood pressure ranges from 65 to 115 systolic, and the diastolic pressure ranges from 42 to 80. The normal systolic blood pressure for a seven-year-old is 87 to 117, and the normal diastolic pressure is 48 to 64. Larger children (heavier and/or taller) have higher blood pressures than do smaller children of the same age. During adolescence, blood pressure continues to vary according to body size.

An adult's blood pressure tends to increase with advancing age. Canadian guidelines indicate that blood pressure should be assessed at all appropriate health care visits. Blood pressure should be treated to lower than 140/90 mm Hg. In those people with diabetes or chronic kidney disease, blood pressure should be treated to below 130/80 mm Hg. Those with high normal blood pressure should be followed up annually to assess for risk of early onset hypertension (Canadian Hypertension

TABLE 30-7

Classification of Blood Pressure for Adults Aged 18 and Older

Category	Systolic Pressure (mm Hg)	Diastolic Pressure (mm Hg)
Optimal	<120	<80
Normal	<130	<85
High normal	130–139	85–89
Grade 1 hypertension	140–159	90–99
Grade 2 hypertension	160–179	100–109
Grade 3 hypertension	≥180	≥110
Isolated systolic hypertension)	>140	<90

Adapted from Canadian Hypertension Education Program. (2008).

Recommendations for the management of hypertension, Part 1: Hypertension as a public health risk. Retrieved from <http://www.hypertension.ca/chep/educational-resources/slides> (Introduction Slide 5).

To keep up to date with the latest evidence and resources for the prevention and control of hypertension, go to <http://www.htnupdate.ca>.

Education Program, 2011; Table 30-7). Older adults may have a rise in systolic pressure that is related to decreased vessel elasticity; however, blood pressure higher than 140/90 is defined as **hypertension** and increases an older adult's risk for hypertension-related illness.

Stress. Anxiety, fear, pain, and other emotional stress results in stimulation of the sympathetic nervous system, which increases heart rate, cardiac output, and peripheral vascular resistance. These alterations, in turn, increase blood pressure. Anxiety can raise blood pressure by as much as 30 mm Hg.

Ethnicity. The incidence of hypertension is higher among ethnic groups such as South Asian, Aboriginal, and Black Canadians. Genetic and environmental factors are believed to be contributing factors (Heart & Stroke Foundation, 2011).

Gender. Males and females do not have clinically significant differences in blood pressure levels. After puberty, boys tend to have higher blood pressure readings. After menopause, women tend to have higher levels of blood pressure than do men of similar ages.

Daily Variation. Blood pressure varies over the course of a day. In people who are active during the day, it is typically lowest during sleep between midnight and 0300 hours (Jones et al., 2006). Between 0300 and 0600 hours, blood pressure rises steadily. Upon awakening, blood pressure surges (Redon, 2004). Blood pressure is highest between 1000 and 1800 hours (Redon, 2004). No two people have the same pattern or degree of variation.

Medications. During blood pressure assessment, it is important to determine if the patient is on any type of medications as some can directly or indirectly affect blood pressure. Antihypertensive or other cardiac medications may lower blood pressure (Table 30-8). Opioid analgesics can lower blood pressure. Vasoconstrictors and an excess of intravenous fluids can increase blood pressure.

Activity, Weight, and Smoking. Blood pressure can be reduced for several hours after a period of exercise. Older adults often experience a 5- to 10-mm Hg fall in blood pressure about one hour after eating. Increases in oxygen demanded by the body during activity leads to increases in blood pressure. Obesity is a factor in hypertension. Smoking results in vasoconstriction. Blood pressure rises when a person is smoking, and it returns to baseline 15 minutes after smoking ceases.

TABLE 30-8

Antihypertensive Medications

Medication Type	Names	Action
Diuretics	Furosemide (Lasix), spironolactone (Aldactone), metolazone, polythiazide, triamterene (Dyazide)	Reduce kidneys' reabsorption of sodium and water, thus lowering circulating fluid volume.
β-Adrenergic blockers	Atenolol (Tenormin), nadolol (Corgard), timolol maleate (Blocadren), propranolol (Inderal)	Combine with β-adrenergic receptors in the heart, arteries, and arterioles to block response to sympathetic nerve impulses; this results in reduced heart rate and thus cardiac output.
Vasodilators	Hydralazine hydrochloride (Apresoline), minoxidil (Loniten)	Act on arteriolar smooth muscle to cause relaxation and reduce peripheral vascular resistance.
Calcium channel blockers	Diltiazem (Cardizem), Dilacor XR), verapamil hydrochloride (Calan SR), nifedipine (Procardia)	Reduce peripheral vascular resistance by systemic vasodilation.
Angiotensin-converting enzyme (ACE) inhibitors	Ramipril (Altace), captopril (Capoten), enalapril (Vasotec), lisinopril (Prinivil, Zestril), benazepril (Lotensin)	Block the conversion of angiotensin I to angiotensin II, which prevents vasoconstriction; also reduces aldosterone production and fluid retention, thereby lowering circulating fluid volume.
Angiotensin II receptor blockers	Losartan (Cozaar), olmesartan (Benicar)	Block the binding of angiotensin II, which prevents vasoconstriction.

Hypertension

The most common alteration in blood pressure is hypertension. Hypertension is often asymptomatic. The diagnosis of high normal blood pressure in adults is made when, on at least two visits to a health care provider after an initial high reading, an average of three or more diastolic readings is between 85 and 89 mm Hg or when the average of multiple systolic blood pressures on two or more subsequent visits is between 130 and 139 mm Hg. Hypertension is noted with diastolic readings higher than 90 mm Hg and systolic readings

BOX 30-13 NURSING STORY

White Coat Hypertension

Between the ages of 45 and 49, my neighbour, M. J., had a blood pressure reading of approximately 140/85 during her annual check-ups. After each visit, I informed her that she may have white coat hypertension and recommended that she monitor her blood pressure at home because individuals who have white coat hypertension are at risk of developing true hypertension. I advised her to reduce her sodium dietary intake and to exercise regularly; she did not drink alcohol. I monitored her blood pressure at home; results were all below 135/85. At her annual checkup after her 50th birthday, her blood pressure was 140/86; at a follow-up visit two months later, it was 142/88. During that time, her blood pressure at home ranged between 136 and 140 (systolic) and 82 and 86 (diastolic). She went to the hypertension clinic to have a 24-hour blood pressure monitor applied. I informed her that this test would provide the physician with information to make treatment decisions. Because of high readings during the test, Dyzide (triamterene), 25 mg daily, was prescribed. I continued to monitor her blood pressure at home, but because her results remained in the hypertensive range, enalapril (Vasotec) 2.5 mg was added to her blood pressure drug regimen at her next visit four months later. Since then, all of her blood pressure readings, both at home and in the physician's office, have been below 126 (systolic) and 82 (diastolic). Four years later, M. J.'s blood pressure continues to be controlled.

higher than 140 mm Hg (Canadian Hypertension Education Program, 2011). Categories of hypertension have been developed and are used to determine medical intervention (see Table 30-7). One elevated blood pressure measurement does not qualify as a diagnosis of hypertension. However, if an elevated reading (e.g., 150/90 mm Hg) is obtained during the first blood pressure measurement, two subsequent readings should be taken. The first reading is discarded and the additional readings are then averaged. If results remain elevated, further medical follow-up is required. Home measurement of blood pressure is an important facet in the diagnosis of white coat hypertension and masked hypertension (Canadian Hypertension Education Program, 2011). In **white coat hypertension**, blood pressure is elevated during a visit to a health care provider. Affected patients are more likely to develop true hypertension over time. In **masked hypertension**, the blood pressure reading is normal while the patient is with a health care provider but becomes elevated at home (Canadian Hypertension Education Program, 2011). Box 30-13 describes a nursing example.

Hypertension is associated with thickening and loss of elasticity in the arterial walls. Peripheral vascular resistance increases within thick, inelastic vessels. The heart must continually pump against greater resistance. As a result, blood flow to vital organs such as the heart, brain, and kidney decreases.

People with a family history of hypertension are at significant risk for developing hypertension and cardiovascular disease. Modifiable risk factors linked to hypertension include obesity, cigarette smoking, heavy alcohol consumption, high sodium (salt) intake, sedentary lifestyle, and continued exposure to stress. The incidence of hypertension is higher among people with diabetes, among older adults, and in some ethnic groups. It is a major factor underlying deaths from strokes and is a factor contributing to myocardial infarctions (heart

attacks). When hypertension is diagnosed, educate the patient about blood pressure values, long-term follow-up care and therapy, the usual lack of symptoms (the fact that it may not be “felt”), the ability of therapy to control but not cure hypertension, and the importance of consistently following a treatment plan to ensure a relatively normal lifestyle (Canadian Hypertension Education Program, 2011).

Hypotension

Hypotension is considered present when the systolic blood pressure decreases to 90 mm Hg or lower. Some adults may have a low blood pressure normally; however, for the majority of people, low blood pressure is an abnormal finding associated with illness.

Hypotension occurs because of the dilation of the arteries in the vascular bed, the loss of a substantial amount of blood volume (e.g., hemorrhage), or the failure of the heart muscle to pump adequately (e.g., myocardial infarction). Hypotension associated with pallor, skin mottling, clamminess, confusion, increased heart rate, or decreased urine output is life-threatening and should be reported to a prescribing health care provider immediately.

Orthostatic hypotension, also referred to as **postural hypotension**, occurs when a normotensive person (a person with normal blood pressure) develops symptoms of low blood pressure when rising to an upright position. When a healthy individual changes from lying down to a sitting or standing position, the peripheral blood vessels in the legs constrict. Vasoconstriction in the lower extremities during standing prevents the pooling of blood in the legs caused by gravity. Thus, no symptoms are normally felt when standing. In contrast, when patients have a decreased blood volume, their blood vessels are already constricted. When a volume-depleted patient stands, blood pressure drops significantly, and heart rate increases to compensate for the drop in cardiac output. Patients who are dehydrated, are anemic, or have experienced prolonged bed rest or recent blood loss are at risk for orthostatic hypotension.

Assess for orthostatic hypotension during vital sign measurements by obtaining blood pressure and pulse with the patient supine, sitting, and standing. The readings are obtained one to three minutes after the patient changes position. In most cases, orthostatic hypotension is detected within a minute of standing up. If it occurs, assist the patient to a lying position and notify the prescribing health care provider or nurse in charge. While obtaining orthostatic measurements, observe for other symptoms of hypotension such as fainting, weakness, or light-headedness. When recording orthostatic blood pressure measurements, record the patient's position, in addition to the blood pressure measurement: for example, “140/80 supine, 132/72 sitting, 108/60 standing.” Because the skill of orthostatic measurements requires advanced reasoning and ongoing nursing judgement, *do not delegate this procedure* to unregulated care providers.

Measurement of Blood Pressure

Arterial blood pressure may be measured either directly (invasively) or indirectly (noninvasively). The direct method requires the insertion of a thin catheter into an artery. Tubing connects the catheter to electronic monitoring equipment. The monitor displays a constant arterial pressure waveform and reading. Because of the risk of sudden blood loss from an artery, invasive blood pressure monitoring is used only in

intensive care settings. The more common noninvasive method requires use of the sphygmomanometer and stethoscope. Measure blood pressure indirectly by auscultation or palpation. Auscultation is the most widely used technique (Skill 30-5).

Blood Pressure Equipment. Before assessing blood pressure, make sure that you know how to use a sphygmomanometer and stethoscope. A **sphygmomanometer** includes a pressure manometer, an occlusive cloth or vinyl cuff that encloses an inflatable rubber bladder, and a pressure bulb with

Text continued on p. 528

► SKILL 30-5 Measuring Blood Pressure

Delegation Considerations

In most provinces and territories, the task of measuring blood pressure can be delegated to unregulated care providers (UCPs). The nurse is responsible for assessing changes in blood pressure; therefore, when the task of measuring blood pressure is delegated, it is important to *inform the unregulated care provider* about the following:

- Selection of appropriate limb for blood pressure measurement—typically the arm, but can also be measured on leg
- Selection of appropriate-size blood pressure cuff for designated extremity
- Frequency of blood pressure measurement for patient
- Patient's usual values
- Abnormalities that should be reported to the health care provider

Procedure

STEPS

1. Determine need to assess patient's blood pressure:
 - A. Note risk factors for alteration in blood pressure, including cardiovascular disease, renal disease, diabetes, circulatory shock, acute or chronic pain, rapid intravenous infusion of fluids or blood products, increased intracranial pressure, postoperative conditions, and toxemia of pregnancy.
 - B. Observe for signs and symptoms of blood pressure alterations.
 - (1) High blood pressure (hypertension): headache (usually occipital), flushing of face, nosebleed, and fatigue (older adults); often asymptomatic until pressure is very high
 - (2) Low blood pressure (hypotension): dizziness, mental confusion; restlessness; pale, dusky, or cyanotic skin and mucous membranes; and cool, mottled skin over extremities
2. Determine best site for blood pressure assessment. Avoid applying cuff to extremity where intravenous fluids are infusing; where an arteriovenous shunt or fistula is present; on the side where breast or axillary surgery has been performed; and when extremity has been traumatized, is diseased, or requires a cast or bulky bandage. Use lower extremities when the brachial arteries are inaccessible.
3. Determine previous baseline blood pressure (if available) from patient's record.
4. Identify factors likely to interfere with accuracy of blood pressure measurement (e.g., acute anxiety, stress, pain). Encourage patient to avoid caffeine, smoking, and nicotine for 60 minutes before blood pressure is assessed (Canadian Hypertension Education Program, 2011).
5. Explain to patient that blood pressure is to be assessed, and have patient rest at least 5 minutes before blood pressure is measured in sitting or lying position; wait 1 minute if patient is standing. Ask patient not to speak when blood pressure is being measured.

Equipment

- Aneroid sphygmomanometer
- Cloth or disposable vinyl pressure cuff of appropriate size for patient's extremity
- Stethoscope
- Alcohol swab
- Pen and either vital sign flow sheet or documentation form

RATIONALE

- Use clinical judgement to determine need for assessment.
- Certain conditions heighten risk for blood pressure alteration.
- Physical signs and symptoms may indicate alterations in blood pressure.
- Inappropriate site selection results in poor amplification of sounds causing inaccurate readings. Application of pressure from inflated cuff bladder temporarily impairs blood flow and can exacerbate existing impairment of circulation in extremity.
- Baseline measurement enables the assessment of change in patient's condition and provides comparison with future blood pressure measurements.
- Exercise and smoking cause false elevations in blood pressure. Smoking increases blood pressure immediately, with the effect lasting up to 15 minutes. Caffeine (e.g., in coffee) increases blood pressure for up to 3 hours.
- These preparations allow patient to relax and help avoid falsely elevated readings. Blood pressure readings taken at different times can be objectively compared with readings taken with patient at rest. Talking to a patient when the blood pressure is being assessed may increase readings (Canadian Hypertension Education Program, 2011).

► SKILL 30-5 Measuring Blood Pressure—cont'd

[video](#)

6. Select appropriate cuff size.
 7. Ensure proper functioning of cuff components: release valve should be clean and freely movable in either direction; inflation bulb and tubing should be intact and free of leaks.
 8. Perform hand hygiene.
 9. Have patient assume sitting or lying position. Be sure room is warm, quiet, and relaxing.
 10. With patient sitting or lying, position patient's forearm at heart level; position patient's thigh flat (provide support as needed). To measure at patient's arm, turn palm up (see Step 10 illustration); to measure at patient's thigh, position with knee slightly flexed. If patient is sitting, instruct patient to sit with feet touching floor without crossing legs (Canadian Hypertension Education Program, 2011).
 11. Expose patient's extremity (arm or leg) fully by removing constricting clothing.
 12. Palpate patient's brachial artery (arm; see Step 12a illustration) or popliteal artery (leg). With cuff fully deflated, apply bladder of cuff above artery by centring cuff over artery. If no centre arrows appear on the cuff, estimate the centre of the bladder and place this centre over artery. Position cuff 2.5 cm above site of pulsation (antecubital or popliteal space). Wrap cuff evenly and snugly around extremity (see Step 12b illustrations). Do not place blood pressure cuff over clothing.
- Improper cuff size results in inaccurate readings. If cuff is too small or comes loose when inflated, this may result in falsely high readings. A cuff that is too large may produce falsely low readings.
 - Improper functionality results in difficulty with regulation of cuff inflation and deflation.
 - Hand hygiene reduces transmission of microorganisms between the patient and the nurse.
 - These actions maintain patient's comfort during measurement. The patient's perceptions that the physical or interpersonal environment is stressful affect the blood pressure measurement.
 - If extremity is unsupported, patient may perform isometric exercise that increases diastolic blood pressure. Leg crossing falsely elevates blood pressure.
 - Exposure ensures proper cuff application.
 - Inflating bladder directly over artery ensures that proper pressure is applied during inflation. Loose-fitting cuff causes false high readings.

Step 10 Patient's forearm supported in bed.

Step 12a Palpating patient's brachial or popliteal artery.

Step 12b Left, Bladder of cuff centred above artery. Right, Blood pressure cuff wrapped around upper arm.

video

13. Position aneroid manometer gauge no further than 1 metre away.

14. Measure blood pressure.

A. Two-step method

- (1) Relocate patient's brachial or popliteal pulse. Palpate the artery distal to the cuff with fingertips of nondominant hand while inflating cuff rapidly to pressure 30 mm Hg above the point at which the pulse disappears. Slowly deflate cuff, and note reading when the pulse reappears. Deflate cuff fully and wait 1 minute.
- (2) Place stethoscope earpieces in your ears, and be sure sounds are clear, not muffled.
- (3) Relocate patient's brachial or popliteal pulse and place bell or diaphragm chest piece of stethoscope over it. Do not allow chest piece to touch cuff or clothing (see Steps 14A[3] illustration).
- (4) Close valve of pressure bulb clockwise until it is tight.
- (5) Rapidly inflate cuff to 30 mm Hg above previously palpated systolic pressure (patient's estimated systolic pressure; see Step 14A[5] illustration).

Step 14A(3) Stethoscope over brachial artery to measure blood pressure.

- (6) Slowly release pressure bulb valve, and allow needle of manometer gauge to fall at rate of 2–3 mm Hg/second. Make sure no extraneous sounds are audible.
- (7) Note point on manometer when first clear sound is heard. The sound will slowly increase in intensity.
- (8) Continue to deflate cuff, noting point at which sound becomes muffled or dampened.
- (9) Continue to deflate cuff gradually, noting point at which sound disappears in adults. Listen for 10–20 mm Hg after the last sound, and then allow remaining air to escape quickly.

B. One-step method

- (1) Place stethoscope earpieces in your ears, and be sure sounds are clear, not muffled.
- (2) Relocate patient's brachial or popliteal artery, and place bell or diaphragm chest piece of stethoscope over it. Do not allow chest piece to touch cuff or clothing.
- (3) Close valve of pressure bulb clockwise until tight. Quickly inflate cuff to 30 mm Hg above palpated systolic pressure.

- Gauge indicates correct readings.

- Provides estimate of systolic pressure, which assists in level of cuff inflation particularly when baseline BP is unknown.
- Relocating prevents false low readings. Maximal inflation point for accurate reading can be determined by palpation. If you are unable to palpate artery because of weakened pulse, an ultrasonic stethoscope can be used (see Chapter 31). Completely deflating cuff prevents venous congestion and false high readings.
- Each earpiece should follow angle of ear canal to facilitate hearing.
- Proper stethoscope placement ensures optimal sound reception. An improperly positioned stethoscope causes muffled sounds that often result in false low systolic readings and false high diastolic readings.
- Tightening of valve prevents air leak during inflation.
- Rapid inflation ensures accurate measurement of systolic pressure.

Step 14A(5) Inflating blood pressure cuff.

- Too rapid or slow a decline in pressure can cause inaccurate readings. Noise interferes with precise determination of Korotkoff phases.
- First Korotkoff sound indicates systolic pressure.
- Fourth Korotkoff sound is distinctly muffled and is indication of diastolic pressure in children.
- Beginning of the fifth Korotkoff sound is indication of diastolic pressure in adults. Cuff is deflated as soon as possible because continuous cuff inflation causes arterial occlusion, resulting in numbness and tingling sensation in patient's arm.
- Used for frequent measurements and when there is previous awareness of systolic inflation level.
- Each earpiece should follow angle of ear canal to facilitate hearing.
- Proper stethoscope placement ensures optimal sound reception. Improper positioning of stethoscope causes muffled sounds that often result in false low systolic readings and false high diastolic readings.
- Tightening of valve prevents air leak during inflation. Inflation above systolic level ensures accurate measurement of systolic pressure.

► SKILL 30-5 Measuring Blood Pressure—cont'd**video**

- (4) Slowly release pressure bulb valve, and allow needle of manometer gauge to fall at rate of 2–3 mm Hg/second.
 - (5) Note point on manometer when first clear sound is heard (1st Korotkoff sound). The sound will slowly increase in intensity.
 - (6) Continue to deflate cuff, noting point at which sound becomes muffled or dampened (4th Korotkoff sound).
 - (7) Continue to deflate cuff gradually, noting point at which the sound disappears (5th Korotkoff sounds) in adults. Listen for 10–20 mm Hg after the last sound, and then allow remaining air to escape quickly.
15. Canadian Hypertension Education Program (2011) recommended that two readings separated by 2 minute should be taken. If readings are different by more than 5 mm Hg, additional readings are necessary.
 16. Remove cuff from extremity unless measurement must be repeated. If patient's blood pressure is being assessed for the first time, repeat blood pressure assessment on other extremity.
 17. Assist patient to return to comfortable position, and cover patient's upper arm if it was previously clothed.
 18. Discuss findings with patient as needed.
 19. Perform hand hygiene.
 20. Compare reading with previous baseline value, acceptable value of blood pressure for patient's age, or both.
- Too rapid or slow a decline in pressure can cause inaccurate readings.
 - First Korotkoff sound indicates systolic pressure.
 - Fourth Korotkoff sound is distinctly muffled and indicates diastolic pressure in children.
 - Beginning of the 5th Korotkoff sound is indication of diastolic pressure in adults. Cuff is deflated as soon as possible because continuous cuff inflation causes arterial occlusion, resulting in numbness and tingling sensation in patient's arm.
 - Two sets of blood pressure measurements help prevent false-positive readings resulting from a patient's sympathetic nerve response (alert reaction). Averaging minimizes the effects of anxiety, which often causes a first reading to be higher than subsequent measurements (Canadian Hypertension Education Program, 2011).
 - By comparing blood pressure in both extremities, circulation problems can be detected. (Difference of 5–10 mm Hg between extremities is normal.)
 - These actions restore patient's comfort and promote sense of well-being.
 - Such discussion promotes patient's participation in care and understanding of health status.
 - Hand hygiene reduces transmission of microorganisms between the patient and the nurse.
 - Evaluate for change in condition and alterations.

Critical Decision Point: In some situations (e.g., critically ill patients or those with peripheral vascular disease), it is often necessary to compare blood pressure readings in both arms, both legs, or all four extremities. If using upper extremities, use the arm with the higher pressure for subsequent assessments, unless this is contraindicated.

21. Correlate blood pressure with data obtained from pulse assessment and other related cardiovascular signs and symptoms.
- Blood pressure and heart rate are interrelated.

Unexpected Outcomes

Blood pressure reading cannot be obtained

Blood pressure is not sufficient for adequate perfusion and oxygenation of tissues

Related Interventions

- Determine whether any immediate crisis is present by measuring pulse and respiratory rate.
- Assess for signs of decreased cardiac output (e.g., weak or thready pulse, confusion, pallor, or cyanosis). If any sign is present, notify nurse in charge or prescribing health care provider immediately.
- Use alternative sites or procedures to obtain blood pressure. Auscultate blood pressure in lower extremity; use a Doppler ultrasonic instrument or a palpation method to obtain systolic measurement.
- Repeat blood pressure measurement with sphygmomanometer. Electronic blood pressure devices are less accurate in conditions of low blood flow.
- Compare blood pressure value with baseline value. A systolic reading of 90 mm Hg is an acceptable value for some patients.
- Position patient in supine position to enhance circulation, and restrict activity if this is the cause of blood pressure to decrease.
- Assess for signs of decreased cardiac output (e.g., weak or thready pulse, confusion, pallor, or cyanosis). If any sign present, notify nurse in charge or prescribing health care provider immediately.
- Increase rate of intravenous infusion, or administer vasoconstrictor medications if ordered.

Continued

► SKILL 30-5 Measuring Blood Pressure—cont'd

video

Blood pressure is elevated above acceptable range

- Repeat measurement in patient's other arm, and compare findings. Verify correct size and placement of cuff.
- Ask colleague to repeat measurement in 2 minutes.
- Observe for related symptoms (e.g., headache, confusion), although symptoms are sometimes not apparent until blood pressure is extremely elevated.
- Report elevated blood pressure to nurse in charge or prescribing health care provider immediately.
- Administer antihypertensive medications as ordered.

Recording and Reporting

- Inform patient of value and need for periodic reassessment of blood pressure.
- Record blood pressure in nurses' notes or vital sign flow sheet. Document blood pressure in nurses' narrative notes after administration of specific therapies.
- Report abnormal findings to nurse in charge or prescribing health care provider.

Home Care Considerations

- Assess home noise level to determine which room will provide the quietest environment for assessing blood pressure.
- Consider using electronic blood pressure cuff in the home if patient has hearing difficulties, adequate financial resources, and adequate dexterity.

Figure 30-13 Wall-mounted aneroid sphygmomanometer.

Figure 30-14 Guidelines for proper blood pressure cuff size. Cuff width should be 20% more than upper arm diameter, or 40% of circumference and two-thirds of arm length.

a release valve that inflates the bladder. Manometers are of two types: aneroid (Figure 30-13) and mercury. Aneroid manometers have the advantages of being safe, lightweight, portable, and compact. The aneroid manometer contains a glass-enclosed circular gauge with a needle that registers millimetre calibrations. Before using the aneroid model, ensure the needle is pointing to zero and that the manometer is correctly calibrated. Aneroid sphygmomanometers require biomedical calibration every six months in order to verify accuracy (Jones et al., 2003).

Mercury manometers, once the "gold standard," are less commonly used because they contain mercury, a hazardous substance. Most municipalities have prohibited the sale or use of mercury-containing devices because of potential hazards. Pressure created by the inflation of the cuff moves the column of mercury upward against the force of gravity. Millimetre calibrations mark the height of the mercury column. To ensure

accurate readings, the mercury column should fall freely as pressure is released and always remain at zero when the cuff is deflated. Measure at the meniscus of the mercury at eye level; looking up or down results in distorted readings.

Cloth or disposable vinyl compression cuffs contain an inflatable bladder and come in several sizes. The size selected is proportional to the circumference of the limb being assessed (Figure 30-14). Ideally, the width of the cuff should be 40% of the circumference (or 20% wider than the diameter) of the midpoint of the limb on which the cuff is used. The bladder, enclosed by the cuff, should encircle at least 80% of the arm of an adult and the entire arm of a child. Position the lower edge of the cuff above the patient's antecubital fossa, allowing room for placement of the stethoscope bell or diaphragm. Many adults require a large-sized cuff. Using the forearm when a large cuff is not available is not recommended (Box

* BOX 30-14

EVIDENCE-INFORMED
PRACTICE GUIDELINEForearm Versus Upper Arm Blood
Pressure Measurements

Amy, a registered nurse, had a patient whose upper arms were not accessible for measuring his blood pressure. She thought that she would use his forearm instead of disturbing him to use one of his thighs. She checked a reliable Internet site and learned that blood pressure measurements taken on the forearm and the upper arm had been compared when patients were supine and when the head of the bed was elevated at 45 degrees. The researchers (Schell et al., 2006) had inquired whether placement of the blood pressure cuff affected systolic and diastolic blood pressure. Blood pressure was measured in 221 medical surgical inpatients at both arm locations in the supine and head-elevated positions. The researchers selected cuff size on the basis of forearm and upper arm circumference. Results indicated a significant difference between upper arm and forearm blood pressure in both positions. Both systolic and diastolic blood pressures differed as much as 33 mm Hg. The study concluded that forearm blood pressure measurements should not be substituted for upper arm blood pressure measurements. On the basis of these findings, Amy decided that she would measure the patient's blood pressure by using one of his thighs.

Application to Nursing Practice

Forearm blood pressure measurements should not be substituted for upper arm blood pressure measurements.

Reference: Schell, K., Lyons, D., Bradley, E., Bucher, L., Seckel, M., Wakai, S., et al. (2006). Clinical comparison of automatic noninvasive measurements of blood pressure in the forearm and upper arm with the client supine or with the head of the bed raised 45 degrees: A follow-up study. *American Journal of Critical Care*, 15, 196–205.

30-14). Keep in mind that blood pressure measurements are not accurate unless the correct size cuff is applied appropriately (Table 30-9).

The release valve of the aneroid or mercury sphygmomanometer should be clean and freely movable in either direction. The valve, when closed, holds the pressure constant. A sticky valve makes pressure cuff deflation hard to regulate. The pressure bulb should be free of leaks.

Auscultation. The best environment for blood pressure measurement by auscultation is a quiet room at a comfortable temperature. Although the patient may lie or stand, sitting is the preferred position. In most patients, blood pressure readings obtained in the supine, sitting, and standing positions are similar.

Patient position should be consistent during routine blood pressure measurements to enable meaningful comparison of values. Before measuring blood pressure, attempt to control factors responsible for artificially high readings, such as pain, anxiety, or exertion. Minimize the patient's perceptions that the physical or interpersonal environment is stressful in order to reduce any effect on blood pressure measurement.

During the initial assessment, measure and record the blood pressure in both arms. Normally, pressures in the arms differ by 5 to 10 mm Hg. In subsequent assessments, measure the blood pressure in the arm with the higher pressure. Pressure differences greater than 10 mm Hg indicate vascular problems and should be reported to the prescribing health care provider or nurse in charge.

> TABLE 30-9

Common Mistakes in Blood
Pressure Assessment

Error

Effect

Bladder or cuff too wide	False low reading
Bladder or cuff too narrow or too short	False high reading
Cuff wrapped too loosely or unevenly	False high reading
Deflating cuff too slowly	False high diastolic reading
Deflating cuff too quickly	False low systolic reading and false high diastolic reading
Arm below heart level	False high reading
Arm above heart level	False low reading
Arm not supported	False high reading
Stethoscope that fits poorly or impairment of the examiner's hearing, causing sounds to be muffled	False low systolic reading and false high diastolic reading
Stethoscope applied too firmly against antecubital fossa	False low diastolic reading
Cuff inflating too slowly	False high diastolic reading
Repeating assessments too quickly	False high systolic reading
Inadequate inflation level	False low systolic reading
Multiple examiners using different Korotkoff sounds for diastolic readings	False high systolic reading and low diastolic reading

Ask the patient to state his or her usual blood pressure. If the patient does not know, inform the patient after measuring and recording the blood pressure. Educate the patient about optimal values of blood pressure, the risk factors for developing hypertension, and the dangers of hypertension.

Indirect measurement of arterial blood pressure works on a basic principle of pressure: blood flows freely through an artery until an inflated cuff applies pressure to tissues and causes the artery to collapse. After the cuff pressure is released, the point at which blood flow returns and sound appears through auscultation is the systolic pressure.

In 1905, Nikolai Korotkoff, a Russian surgeon, first described the sounds heard over an artery distal to the blood pressure cuff. The first Korotkoff sound is a clear rhythmical tapping that corresponds to the pulse rate and gradually increases in intensity. *Onset of the sound corresponds to the systolic pressure.* A blowing or swishing sound occurs as the cuff continues to deflate; this is the second Korotkoff sound. As the artery distends, blood flow becomes turbulent. The third Korotkoff sound is a crisper and more intense tapping. The fourth Korotkoff sound is muffled and low-pitched as the cuff is further deflated. At this point, the cuff pressure has fallen below the pressure within the vessel walls; *this sound is the diastolic pressure in infants and children.* The fifth Korotkoff "sound" is actually the disappearance of sound. *In adolescents and adults, the fifth sound corresponds to the diastolic pressure* (Figure 30-15). In some patients, the sounds are clear and distinct. In other patients, only the beginning and ending sounds are clear.

The Canadian Hypertension Education Program (2011) recommended recording two numbers for blood pressure measurement: the point on the manometer when the first sound is heard (systolic reading), and the point on the manometer when the fifth sound is heard (diastolic reading). Some institutions recommend recording the point when the fourth sound is

Figure 30-15 The sounds auscultated during blood pressure measurement can be differentiated into five Korotkoff phases. In this example, blood pressure is 140/90.

heard as well, especially for patients with hypertension. Present the numbers by slashed lines (e.g., “120/80” or “120/100/80”). Note the arm used to measure the blood pressure (e.g., “right arm [RA] 130/70”), and the patient’s position (e.g., “sitting”).

Blood pressure findings prompt many medical decisions and nursing interventions concerning a patient’s health care. Obtaining an accurate blood pressure measurement is essential. Error can arise from several sources (see Table 30-9). When unsure of a reading, ask a colleague to reassess the blood pressure.

Assessment in Children. All children three years of age through adolescence should have blood pressure checked at least yearly. Blood pressure in children changes with growth and development. Help parents understand the importance of this routine screening in children who may be at risk for hypertension.

The measurement of blood pressure in infants and children is difficult for several reasons:

- Different arm sizes necessitate careful selection of appropriate cuff size. Do not choose a cuff on the basis of the name of the cuff; for example, an “infant” cuff may be too small for some infants.
- Readings are difficult to obtain in restless or anxious infants and children. Allow a delay of at least 15 minutes to recover from recent activities and apprehension.
- Preparing the child for the blood pressure cuff’s unusual sensation can increase cooperation. Most children understand the analogy of a “tight hug on your arm.”
- Placing the stethoscope too firmly on the antecubital fossa causes errors in auscultation.

BOX 30-15 Procedural Guideline

Palpating the Systolic Blood Pressure

Delegation Considerations:

The skill of palpation of blood pressure *may not be delegated* to unregulated care providers.

Equipment:

Sphygmomanometer.

Procedure:

1. Perform hand hygiene.
2. Apply the blood pressure cuff to the patient’s extremity selected for measurement.
3. Continually palpate the pulse of the patient’s brachial, radial, or popliteal artery with fingertips of one of your hands.
4. Rapidly inflate the blood pressure cuff 30 mm Hg above the point at which the patient’s pulse cannot be palpated.
5. Slowly release the valve and deflate the cuff at a rate of 2 to 3 mm Hg per second.
6. Note the manometer reading when the pulse is again palpable; this is the systolic blood pressure.
7. Deflate the cuff rapidly and completely. Remove the cuff from the patient’s extremity unless repeat measurement is needed.
8. Perform hand hygiene. Record pressure as “[systolic]/—” and palpated (e.g., “blood pressure 108/—, palpated”).

- Korotkoff sounds are difficult to hear in children because of low frequency and amplitude. A pediatric stethoscope bell can be helpful. The fourth Korotkoff sound, which is typically quite muffled, represents the diastolic pressure in infants and children.

Ultrasonic Stethoscope. If you are unable to auscultate sounds because of a weakened arterial pulse, an ultrasonic stethoscope can be used (see Chapter 31). This stethoscope enables you to hear low-frequency systolic sounds. It is commonly used for measuring the blood pressure of infants, children, and adults with low blood pressure.

Palpation. The indirect palpation technique is useful for patients whose arterial pulsations are too weak to create Korotkoff sounds. Severe blood loss and decreased heart contractility are examples of conditions that result in blood pressure too low to auscultate accurately. In these cases, the systolic blood pressure can be assessed by palpation; the diastolic pressure, however, is difficult to assess by palpation (Box 30-15). When using the palpation technique, record the systolic value and how it was measured (e.g., “RA 90/—, palpated, supine”).

The palpation technique can be used with auscultation. In some hypertensive patients, the sounds usually heard over the brachial artery when the cuff pressure is high disappear as pressure is reduced, and then they reappear at a lower level. This temporary disappearance of sound is the **auscultatory gap**. It typically occurs between the first and second Korotkoff sounds. The gap in sound may cover a range of 40 mm Hg and thus may cause you to underestimate systolic pressure or overestimate diastolic pressure. You must be certain to inflate the cuff high enough to hear the true systolic pressure before the auscultatory gap. Palpation of the radial artery helps you determine how high to inflate the cuff. Inflate the cuff to 30 mm Hg above the pressure at which the radial pulse disappeared and rapidly deflate the cuff. Record the range of

Figure 30-16 Lower extremity blood pressure cuff positioned above the popliteal artery at midthigh with knee flexed. **Source:** Courtesy St. Mary's Health Center, St. Louis, MO.

pressures in which the auscultatory gap occurs (e.g., “blood pressure RA 180/94 with an auscultatory gap from 180 to 160, sitting”).

Lower Extremity Blood Pressure. Dressings, casts, intravenous catheters, arteriovenous fistulas, or shunts can render the upper extremities inaccessible for blood pressure measurement. In such cases, blood pressure is measured in the lower extremities. Comparing upper extremity blood pressure with that in the legs is also necessary for patients with certain cardiac or blood pressure abnormalities. The popliteal artery, palpable behind the knee in the popliteal space, is the site for auscultation. The cuff must be wide and long enough to allow for the larger girth of the thigh. Placing the patient in a prone position is best. If such a position is impossible, ask the patient to flex the knee slightly for easier access to the artery. Position the cuff 2.5 cm above the patient's popliteal artery with the bladder over the posterior aspect of the midthigh (Figure 30-16). The procedure is identical to that for brachial artery auscultation. Systolic pressure in the legs is usually 10 to 40 mm Hg higher than in the brachial artery, but the diastolic pressure should be the same.

Automatic Blood Pressure Devices. Many styles of electronic devices are available to determine an automatic blood pressure assessment rather than manual (Figure 30-17). For example, some devices rely on an electronic sensor to detect the vibrations caused by the rush of blood through an artery. When the cuff deflates, the sensor determines the initial burst of vibrations and translates the information into a systolic pressure reading. When the vibrations are lowest, just before they stop, the diastolic pressure is determined. Use electronic blood pressure machines when frequent blood pressure assessment is required, as in critically ill or potentially unstable patients; during or after invasive procedures; or when therapies necessitate frequent monitoring (e.g., intravenous medications for cardiac and blood pressure conditions; Box 30-16). For some patient conditions, the use of automatic blood pressure devices is not appropriate (Box 30-17).

Automatic devices are easy to use and efficient when measurements must be repeated or frequent. The ability to use a stethoscope is not required. However, automatic devices are more sensitive to outside interference, and their readings are susceptible to error. Most automatic blood pressure devices cannot process sounds or vibrations of low blood pressure. The

Figure 30-17 Automatic blood pressure monitor. **Source:** Photo courtesy of Welch Allyn, www.welchallyn.com

range of device sophistication also can make blood pressure measurement comparisons difficult. The use of automatic blood pressure devices enables assessment of blood pressure during interpersonal interactions. However, avoid speaking to the patient for at least a minute before you initiate a blood pressure recording. Talking to a patient when the blood pressure is being assessed can increase readings 10 to 40%.

Obtain a baseline blood pressure measurement by using the auscultatory method before applying automatic devices. A comparison assists in evaluation of a patient's status and allows proper programming of the device. Once the blood pressure cuff is applied, program the device to obtain and record blood pressure readings at preset intervals. Alarm limits can be programmed to alert you if the blood pressure measurement is outside desired parameters.

Self-Measurement of Blood Pressure. More people measure their own blood pressure because of improved technology in home-monitoring devices and a greater interest in health promotion. Portable home devices include aneroid sphygmomanometers and electronic digital readout devices that do not require use of a stethoscope. The electronic devices inflate and deflate cuffs with the push of a button. The electronic devices are easier to manipulate but can require recalibration more than once a year. Because of their sensitivity, improper cuff placement or movement of the arm causes electronic devices to give incorrect readings.

Stationary automatic blood pressure devices can be found in public places such as grocery stores, drug stores, fitness

► BOX 30-16 Procedural Guideline

Electronic Blood Pressure Measurement

Delegation Considerations:

The task of obtaining an electronic blood pressure measurement can be delegated to an unregulated care provider unless the patient is considered unstable or needs close monitoring. The nurse is responsible for assessing the impact of changes in blood pressure; therefore, when the task of obtaining an electronic blood pressure measurement is delegated, it is important to *ensure that the unregulated care provider* performs the following tasks:

- Selects appropriate limb for measurement.
- Selects appropriate-size cuff for designated limb.
- Selects blood pressure cuff recommended by manufacturer.
- Obtains blood pressure measurement for patient with ordered frequency.
- Reports abnormalities.

Equipment:

Electronic blood pressure machine and blood pressure cuff of appropriate size as recommended by manufacturer.

Procedure:

1. Determine appropriateness of using electronic blood pressure measurement. This device is not suitable for use in patients with irregular heart rates, peripheral vascular disease, seizures, tremors, or shivering.
2. Determine best site for cuff placement (see Skill 30-5, Step 2).
3. Select appropriate cuff size for patient's extremity and appropriate cuff for machine. Electronic blood pressure cuff and machine are matched by the manufacturer and are not interchangeable.
4. Assist patient to comfortable position, either lying or sitting. Plug in device, and place near patient, ensuring that the connector hose between the cuff and machine will reach the patient.
5. Prepare blood pressure cuff by manually squeezing all air out of the cuff and connecting cuff to connector hose.
6. Turn on machine to enable device to perform a self-test on internal computer systems.
7. Expose patient's extremity for measurement by removing restrictive clothing, to ensure proper cuff application. Do not place blood pressure cuff over clothing.
8. Wrap flattened cuff snugly around patient's extremity, verifying that only one finger fits between cuff and patient's skin. Make

sure the "artery" arrow marked on the outside of the cuff is correctly placed.

9. Verify that connector hose between cuff and machine is not kinked. Kinking prevents proper inflation and deflation of cuff.
10. In accordance with manufacturer's directions, set frequency control to automatic or manual, and then press "start" button. The first blood pressure measurement will pump the cuff to a pressure of about 180 mm Hg. After this pressure is reached, the machine begins a deflation sequence that helps measure the blood pressure. The first reading is the peak pressure inflation for additional measurements.
11. When deflation is complete, digital display provides most recent values and flashes time (in minutes) that has elapsed since measurement occurred.
12. Set frequency of blood pressure measurements and upper and lower alarm limits for systolic, diastolic, and mean blood pressure readings. Intervals between blood pressure measurements can be set from 1 to 90 minutes. Determine measurement frequency and alarm limits on the basis of patient's acceptable range of blood pressure, your nursing judgement, and health care provider's order.
13. Obtain additional readings at any time by pressing the start button. (Sometimes you need these readings for unstable patients.) Pressing the "cancel" button immediately deflates the cuff.
14. If blood pressure determinations must be frequent, leave the cuff in place. Remove cuff at least every two hours to assess underlying skin integrity, and, if possible, alternate blood pressure sites. Patients with abnormal bleeding tendencies are at risk for microvascular rupture from repeated inflations. When electronic blood pressure machine is no longer needed, clean cuff according to facility policy to reduce transmission of microorganisms between patients.
15. Compare electronic blood pressure readings with auscultatory blood pressure measurements to verify accuracy of the electronic blood pressure device.
16. Record blood pressure and site assessed on vital sign flow sheet or in nurses' notes. Record associated signs of blood pressure alterations in nurses' progress notes. Report abnormal findings to nurse in charge or health care provider.

► BOX 30-17

Patient Conditions Not Appropriate for Electronic Blood Pressure Measurement

- Irregular heart rate
- Peripheral vascular obstruction (e.g., clots, narrowed vessels)
- Shivering
- Seizures
- Excessive tremors
- Inability of patient to cooperate
- Systolic blood pressure of less than 90 mm Hg

clubs, airports, and worksites. Users rest their arms within the machine's inflatable cuff, which contains a pressure sensor. The cuff fits over clothing. A visual display tells users their blood pressure within 60 to 90 seconds. The reliability of the stationary machines is limited. Blood pressure values

(both systolic and diastolic) may vary by 5 to 10 mm Hg or more in comparison with values measured by a manual sphygmomanometer.

Self-measurement of blood pressure has several benefits. Elevated blood pressure may be detected in people previously unaware of a problem. People with high normal blood pressure can provide information about the pattern of blood pressure values. Patients with hypertension can benefit from actively participating in their treatment through self-monitoring, which may subsequently enhance compliance with treatment. The disadvantages of self-measurement include improper use of the device and inaccurate readings. A patient may be needlessly alarmed by one elevated reading. Patients with hypertension may become overly conscious of their blood pressure and inappropriately adjust medication intake.

Patients can learn to use self-measurement devices if they have the information needed to perform the procedure correctly and know when to seek medical attention. Advise

patients that because of possible inaccuracies in the blood pressure devices, they must not adjust their medication regimens without consulting the health care provider. It is important to teach patients the meaning and implications of readings and ensure understanding of proper measurement techniques.

Nursing Process and Blood Pressure Determination

In assessing blood pressure and pulse, the patient's general state of cardiovascular health and responses to other system imbalances can be evaluated. Hypotension, hypertension, orthostatic hypotension, and narrow (small difference) or wide (large difference) pulse pressures are defining characteristics of certain nursing diagnoses, including the following:

- *Activity intolerance*
- *Anxiety*
- *Decreased cardiac output*
- *Deficient/excess fluid volume*
- *Risk for injury*
- *Acute pain*
- *Ineffective tissue perfusion*

The nursing care plan includes interventions specific for the nursing diagnosis identified and the related factors. For example, the defining characteristics of hypotension, dizziness, pulse deficit, and dysrhythmia lead to a diagnosis of *decreased cardiac output*. Related factors may include poor oral intake, excessive heat exposure, and a history of valvular heart disease. The related factor guides the choice of nursing interventions. Evaluate patient outcomes by assessing the blood pressure after each intervention.

Health Promotion and Vital Signs

The emphasis on health promotion and health maintenance, as well as early discharge from hospital settings, has resulted in an increase in the need for patients and their families to monitor vital signs in the home. Teaching considerations affect all vital sign measurements. Incorporate them within the patient's plan of care (Boxes 30-18 and 30-19). Recording Vital Signs

Measurements of vital signs can be recorded on graphic flow sheets (and/or in progress notes). Identify institutional procedures for documenting on the graphic or vital sign flow sheet. In addition to the actual vital sign values, record in the progress notes any accompanying or precipitating symptoms, such as chest pain and dizziness with abnormal blood pressure, shortness of breath with abnormal respiration, cyanosis with hypoxemia, or flushing and diaphoresis with elevated temperature. Document any interventions initiated as a result of abnormal vital sign measurements, such as administration of oxygen therapy or an antihypertensive medication.

For patients for whom critical paths or care maps are used, vital sign values may be listed as outcomes (see Chapter 12). If a vital sign value is higher or lower than the anticipated outcomes, write a variance note to explain the nature of the variance and your course of action. For example, a care map for a patient who has undergone a thoracotomy may list a postoperative outcome of "afebrile." If the patient has a fever, the nurse's variance note addresses possible sources of fever (e.g., retained pulmonary secretions) and nursing interventions (e.g., increased suctioning, postural drainage, or hydration).

* BOX 30-18 FOCUS ON PRIMARY HEALTH CARE

Health Promotion and Vital Signs

Temperature

- Identify patient's ability to initiate preventive health care and recognize alteration in body temperature. Educate patient and caregiver about ways to prevent body temperature alterations.
- Teach patients risk factors for hypothermia and frostbite: fatigue; malnutrition; hypoxemia; cold, wet clothing; and alcohol intoxication.
- Teach patients risk factors for heat stroke: strenuous exercise in hot, humid weather; sudden exposure to hot climates; insufficient fluid intake before, during, and after exercise.
- Teach patients importance of taking and continuing to take antibiotics as directed until course of treatment is completed (e.g., to decrease chance of resurgence of infection or the development of antibiotic-resistant organisms).

Pulse Rate

- Patients taking certain cardiac medications need to learn to assess their own pulse rates to detect side effects.
- Patients undergoing cardiac rehabilitation need to learn to assess their own pulse rates to determine their response to exercise.

Blood Pressure

- Patients with family history of hypertension are at significant risk for hypertension. Teach risk factors for hypertension: obesity, cigarette smoking, heavy alcohol consumption, high blood cholesterol and triglyceride levels, and continued exposure to stress.
- Patients with hypertension need to learn about their blood pressure values, long-term follow-up care and therapy, the lack of obvious symptoms indicative of high blood pressure, ability of

therapy to control but not cure hypertension, and benefits of consistently following treatment plan.

- Teach patient importance of appropriate-sized blood pressure cuff for home use.
- Instruct patient or primary caregiver to measure blood pressure at same time each day and after patient has had a brief rest. Patients should measure blood pressure while sitting or lying down, and they should use the same position and arm each time they measure pressure.
- Instruct patient or primary caregiver that if it is difficult to hear the pressure, the cuff may be too loose, not big enough, or too narrow; the stethoscope is not over arterial pulse; the cuff was deflated too quickly or too slowly; or the cuff was not pumped high enough for systolic readings.

Respirations

- Patients who demonstrate decreased ventilation benefit from learning deep breathing and coughing exercises (see Chapter 48).
- Instruct patient or caregiver to contact home care nurse or prescribing health care provider if unusual fluctuations in respiratory rate occur.
- Teach patient signs and symptoms of hypoxemia: headache, somnolence, confusion, dusky colour of skin and mucous membranes, shortness of breath, and dyspnea.
- Teach patient effect of high-risk behaviours on respiratory function—cigarette smoking, environmental pollutants, etc.

When considering how to teach patients and their families about vital sign measurements and their importance and significance, the patient's age is an important factor. Because of the increase in the population of older adults, caregivers must be more aware of changes that are unique to older adults. Box 30-19 identifies some of these variations.

* BOX 30-19 FOCUS ON OLDER ADULTS

Vital Signs

Temperature

- Normal body temperature ranges from 36°C to 36.8°C orally and 36.6°C to 37.2°C rectally. Temperatures considered to be within normal range sometimes reflect a fever in an older adult.
- Older adults are very sensitive to slight changes in environmental temperature because their thermoregulatory systems are not as efficient (Ebersole et al., 2004).
- Sweat gland reactivity decreases in older adults; as a result, sweating may not occur until temperatures are very high, leading to hyperthermia and heatstroke.
- Loss of subcutaneous fat reduces the insulating capacity of the skin; older men are especially at high risk for hypothermia.
- For older adults, be especially attentive to subtle temperature changes and other manifestations of fever, such as tachypnea, anorexia, falls, delirium, and decline in overall function.

Pulse Rate

- If it is difficult to palpate the pulse of an older adult or an obese patient, a Doppler device provides a more accurate reading.
- Older adults have a decreased heart rate at rest (Ebersole et al., 2004).
- In older adults, it takes longer for the pulse rate to rise to meet sudden increased demands that result from stress, illness, or excitement. Once elevated, the pulse rate of an older adult takes longer to return to normal resting rate (Ebersole et al., 2004).
- Heart sounds are sometimes muffled or difficult to hear in older adults because of an increase in air space in the lungs.

Blood Pressure

- In older adults with decreased upper arm mass, blood pressure cuff size must be selected especially carefully.

- The normal range for blood pressure is the same in older adults as in younger adults. An older adult's blood pressure may elevate with age. Such elevations should not be considered a normal aspect of aging; minor elevations in older adults must be monitored (Chobanian et al., 2003).
- Older adults may have an increase in systolic pressure in relation to decreased vessel elasticity. The diastolic pressure remains the same, which results in a wider pulse pressure.
- Instruct older adults to change position slowly and wait after each change before beginning activity, to avoid orthostatic hypotension and prevent injuries.

Respirations

- Aging causes ossification of costal cartilage and causes the ribs to slant downward, which result in more rigidity of the rib cage, which in turn reduces chest wall expansion. Kyphosis and scoliosis that can occur in older adults restrict chest expansion and decreases tidal volume.
- Older adults depend more on accessory abdominal muscles during respiration than on weaker thoracic muscles.
- The respiratory system matures by the time a person reaches the age of 20 and begins to decline in healthy people after the age of 25. Despite this decline, older adults are able to breathe effortlessly as long as they are healthy. Sudden events that increase demand for oxygen (eg., stress, exercise, illness) lead to shortness of breath in the older adult (Ebersole et al, 2004).
- Identifying an acceptable site for the pulse oximeter probe may be difficult in older adults because of the likelihood of peripheral vascular disease, decreased cardiac output, cold-induced vasoconstriction, and anemia.

❖ KEY CONCEPTS

- Vital sign measurement includes the physiological measurement of temperature, pulse, blood pressure, respiration, and oxygen saturation.
- Vital signs are measured as part of either a complete physical examination or a review of a patient's condition.
- Changes in vital signs are evaluated with other physical assessment findings; clinical judgement is used to determine frequency of measurement.
- Knowledge of the factors influencing vital signs assists in determining and evaluating abnormal values.
- Vital signs provide a basis for evaluating response to nursing and medical interventions.
- Vital signs should be measured when the patient is inactive and the environment is controlled for comfort.
- Patients should be assisted in maintaining body temperature by interventions that promote heat loss, production, or conservation.
- A fever is one of the body's normal defence mechanisms.
- Measurement of temperature with the temporal artery is the least invasive, most accurate method of obtaining core temperature.
- Respiratory assessment includes determining the effectiveness of ventilation, perfusion, and diffusion.
- Assessment of respiration involves observing ventilatory movements through the respiratory cycle.

- Variables affecting ventilation, perfusion, and diffusion influence oxygen saturation.
- Pulse rate and rhythm, measured at the radial or apical pulses, are documented to assess cardiac function.
- Hypertension is diagnosed only after an average of readings made during at least three visits to a health care provider reveals elevated blood pressure.
- Improperly selecting and applying the blood pressure cuff results in measurement errors.
- Changes in one vital sign often influence characteristics of the other vital signs.

❖ CRITICAL THINKING EXERCISES

1. A 47-year-old Aboriginal man is visiting the health clinic for a routine physical examination by the nurse practitioner. The unregulated care provider obtains the following vital sign measurements: tympanic temperature, 36.9°C; right radial pulse rate, 96 beats per minute and irregular; blood pressure, sitting, right arm, 162/82 mm Hg, and left arm, 150/70 mm Hg; SpO₂, 95% on room air; respiratory rate, 22 breaths per minute.
 - a. As the admitting nurse, what questions would you ask this patient to evaluate his risk for hypertension?
 - b. On the basis of these vital sign measurements, what actions should you take?

2. A teenaged mother brings her three-year-old son to the walk-in health centre. She notes that he has been fussy, has not had much of an appetite, and is "not his active self." The boy is crying and struggling to get out of his mother's lap during the interview. You note that he is small for his age but his physical development is otherwise normal.
 - a. Describe the sequence you would use for obtaining vital signs.
 - b. When you select the appropriate equipment for measuring the vital signs, what, if any, special considerations are needed?
 - c. The unregulated care provider reports she has obtained a temperature reading of 37.7°C. What additional information do you request from the unregulated care provider?
3. A 52-year-old woman is admitted to the medical unit for chronic dyspnea and discomfort in her left chest with deep breathing and coughing. She has been smoking for 35 years and has a 20-year history of emphysema. Over the past four months, she has lost 4.5 kg and currently weighs 50 kg.
 - a. When delegating the measurement of vital signs to an unregulated care provider, what information and directions should you provide?
 - b. The blood pressure and heart rate are within acceptable ranges. The temperature is 37.5°C, obtained with an oral electronic thermometer; the respiratory rate is 32 breaths per minute and shallow; and the SpO₂ is 89%. On the basis of these results, list your actions in priority order.
4. An 82-year-old resident in a subacute extended-care facility is being treated for pneumonia with antibiotics. She has been on bed rest for the past two days. She has a history of hypertension, treated with diuretics, but is otherwise healthy. She has been afebrile for the past 24 hours and is eager to walk to the activity room. She has activity orders "up ad lib."
 - a. Should an unregulated care provider be delegated to assist with ambulation?
 - b. What places this patient at risk for fainting?
 - c. Why should the nurse obtain orthostatic measurements?
5. A 25-year-old woman arrives at the prenatal clinic for her first visit. She is eight months pregnant. The unregulated care provider checks her vital signs, height, and weight. The patient weighs 104 kg and is 160 cm tall; blood pressure in her right arm is 210/92 mm Hg; her heart rate is 104 beats per minute; her respiratory rate is 24 breaths per minute; her tympanic temperature is 37.1°C. You are concerned about the patient's blood pressure. In repeating the measurement, you obtain 148/86 mm Hg in the right arm and 144/84 mm Hg in the left arm.
 - a. What blood pressure measurement should be recorded? Provide some possible explanations for the difference between your measurements and those obtained by the unregulated care provider.
 - b. What might you explain about the abnormal vital signs to the patient?
 - c. What will be included in your discharge teaching?
6. A pulse deficit provides information about the heart's ability to adequately perfuse the body. A pulse deficit is
 1. The difference between the radial and apical pulse rates
 2. The digital pressure felt when radial and ulnar pulses are measured
 3. The amount of pressure felt when radial and ulnar pulses are measured
 4. The difference between the systolic and diastolic blood pressure readings
7. As individuals approach older adulthood, body temperature tends to
 1. Gradually decrease
 2. Gradually increase
 3. Fluctuate
 4. Remain the same
8. If a blood pressure cuff is too small, the blood pressure reading is
 1. Falsely low
 2. Falsely high
 3. Difficult to hear because sounds are muffled
 4. Dependent on the examiner's hearing acuity
9. Patients with apnea experience
 1. Difficult respiration that requires more effort
 2. Slowness of breathing, followed by rapid breathing
 3. Cessation of breathing that may be temporary
 4. Lack of oxygen to body tissues and organs
10. When teaching patients about management of hypertension, focus of topics should include all of the following except
 1. Diet modification
 2. Self-measurement of BP and acceptable range of results
 3. Self-adjustment of antihypertensive medications
 4. Stress management
11. An older adult recently on bed rest is assisted out of bed. The nurse measures his blood pressure as the patient changes position, and the results are as follows: 140/80 supine, 132/72 sitting, 108/60 standing. The patient also mentions that he feels light-headed. The nurse should immediately
 1. Assist the patient to return to a supine position
 2. Obtain a blood pressure measurement in the other arm
 3. Report the findings to the nurse in charge
 4. Help the patient walk
12. A nurse is measuring a patient's vital signs. The nurse notes that the radial pulse is initially strong, diminishes in intensity, and has an interruption in rhythm about every four to six beats. The nurse should immediately
 1. Report the findings to a health care provider
 2. Measure the apical pulse for 60 seconds
 3. Connect the patient to a cardiac monitor
 4. Measure apical and radial pulse rates simultaneously for 60 seconds
13. Nursing interventions such as applying cool cloths act to decrease body temperature through
 1. Conduction
 2. Convection
 3. Evaporation
 4. Radiation

❖ REVIEW QUESTIONS

1. During a nursing assessment, an adult patient is noted to have shallow respirations at a rate of eight per minute. His heart rate is 46 beats per minute. His vital signs would be described as
 1. Bradycardia and apnea
 2. Tachycardia and apnea
 3. Bradycardia and bradypnea
 4. Tachycardia and bradypnea

10. Poor oxygenation of the blood ordinarily affects the pulse rate, causing it to become
 1. Bounding
 2. Irregular
 3. Faster than normal
 4. Slower than normal
11. When measuring oxygen saturation, all of the following can influence the reading, resulting in inaccurate results, except for
 1. Rapid heart rate, reduced circulation to extremities
 2. Nail polish, tremors
 3. Decreased respiratory depth and effort
 4. Bright light near measuring site
12. Which of these basic techniques are used to determine vital signs?
 1. Inspection, palpation, and auscultation
 2. Inspection, blood work, and radiography
 3. Rhythm and rate measurements and open communication
 4. Psychology, physiology, and nursing skills

❖ RECOMMENDED WEB SITES

Canadian Hypertension Society: <http://www.hypertension.ca/>

This Web site has links to three key organizations dealing with hypertension in Canada: (1) the Canadian Hypertension Society (CHS), (2) the Canadian Hypertension Education Program (CHEP), and (3) Blood Pressure Canada (BPC). The site offers information on hypertension to health providers and the public. It also includes valuable links to related topics (e.g., Heart and Stroke Canada). The mission of CHS is to promote the prevention and control of hypertension through research and education. CHEP is a volunteer, nonprofit hypertension

education program that provides annually updated, relevant, evidence-informed hypertension guidance. BPC is committed to providing high-quality educational material and sources for patients. All sites provide educational tools.

Centre for Chronic Disease Prevention and Control: Cardiovascular Disease: <http://www.phac-aspc.gc.ca/cd-mc/cvd-mcv/index-eng.php>

This Web page, part of the Web site of the Public Health Agency of Canada, provides links to a variety of Canadian resources on cardiovascular health, including the Heart and Stroke Foundation of Canada and the Canadian Stroke Network.

British Columbia Ministry of Health Services, Guidelines and Protocols Advisory Committee (GPAC): Hypertension—Detection, Diagnosis and Treatment of Hypertension: http://www.bcguidelines.ca/gpac/submenu_cardio.html

Part of the British Columbia Ministry of Health Services, the Guidelines and Protocols Advisory Committee developed several documents to recommend proper blood pressure management, including the recommended technique for measuring blood pressure. Other topics are home blood pressure monitoring, dietary approaches, and a patient guide.

Heart & Stroke Foundation of Alberta, Northwest Territories, and Nunavut: Healthy Living: http://www.heartandstroke.ab.ca/site/c.lqIRL1PJtH/b.3650753/k.F791/Heart_Disease_Stroke_and_Healthy_Living.htm

Sponsored by the Public Health Agency of Canada (Health Canada) and the Heart and Stroke Foundation of Canada, this Web site provides information on several blood pressure and heart disease.

Health Assessment and Physical Examination

Original chapter by Rhonda W. Comrie, PhD, RN, CNE, AE-C

Canadian content written by Mary Ellen Andrews, RN(NP), PhD, and Denise Tarlier, PhD, NP(F)

objectives

Mastery of content in this chapter will enable you to:

- Discuss the purposes of physical assessment.
- Discuss cultural diversity, cultural competency, and cultural safety as these relate to the provision of culturally competent health and physical assessment and improved patient health outcomes.
- Identify data to collect from the nursing history before a physical examination.
- Describe environmental preparations necessary prior to a physical examination.
- List techniques used to prepare a patient physically and psychologically before and during an examination.
- Demonstrate the techniques used with each physical assessment skill.
- Describe physical measurements made in assessing each body system.
- Discuss normal physical findings in a young, a middle-aged, and an older adult.
- Identify preventive screenings and the appropriate age(s) for each screening to occur.
- Identify self-screening examinations commonly performed by patients.
- Discuss ways to incorporate health promotion and health teaching into the examination.
- Identify how nurses use physical assessment skills during routine nursing care.

A holistic assessment of a patient's health status involves the collection of a broad range of data that includes information about the emotional, intellectual, physical, psychosocial, and spiritual dimensions (see Chapter 15) and the cultural (see Chapter 9) dimensions. The process for collecting data about a patient includes a thorough health history and the physical examination. The physical exam, although primarily focused on physiological function, may also include assessment of cognition, mood, and functional status.

As a front-line health care worker, a nurse is sometimes the first person with whom patients are in contact when they are provided with health care services. It is, therefore, extremely important that nurses be able to detect changes in a patient's condition. Whether the nurse is conducting health assessments at health fairs, at screening clinics, in physicians' offices, in acute care agencies, or in a patient's home, nurses continuously seek information about patients' health status. For this reason, the ability to critically think and interpret the meaning of a patient's behaviour and physiological status is a skill that is important in professional nursing practice.

The skills of physical assessment and examination provide powerful tools to detect subtle, as well as obvious, changes in a patient's health. Physical assessment enables the nurse to assess patterns reflecting health problems and to evaluate the patient's progress following therapy. Health screenings may focus on a specific physical problem or assess cognition, mood, and functional status. For example, nurses perform blood pressure screenings to detect the risk for high blood pressure, or a nurse may use a depression screening tool to detect alterations in mood. If screening determines that a patient has a risk for a disease or disorder, the nurse refers the patient for a more complete physical examination.

A complete health assessment involves a nursing history (see Chapter 12), a behavioural and physical examination, and a cultural assessment (see Chapter 9). The health history involves a lengthy patient interview to gather subjective data about the patient's condition. The focus of this chapter is an introduction to the skills necessary to perform a physical examination. For a more comprehensive study on physical assessment skills, refer to Jarvis et al. (2009), *Physical Examination and Health Assessment*, First Canadian Edition.

A complete physical examination is a head-to-toe review of each body system that offers objective information about the patient. This allows the nurse to make clinical judgements and develop the plan for nursing care. The patient's condition and response affect the extent of the examination. The accuracy of the physical assessment will influence the choice of therapies a patient receives and the evaluation of the response to those therapies. Continuity in health care improves when the nurse makes ongoing, objective, and comprehensive assessment.

Social and Cultural Considerations

Culturally competent health and physical assessment requires the nurse to be culturally aware and sensitive (see Chapter 9). The nurse demonstrates cultural competence, in part, by respecting patient preference when completing an examination, whether this is based on individual or cultural preference. It is important to remember that social or cultural background may influence a patient's behaviour and beliefs about health. Integrating cultural assessment with health and physical assessment for every patient (see Chapter 9) provides the nurse with the background data needed to facilitate a

culturally competent physical examination. Assessment data about the use of complementary or folk therapies, dietary preferences, family relationships (including extended family), and past experiences with health care offer important clues to help the nurse better understand how to perform physical assessment in ways that are respectful of these preferences and help build relational practice. Ethnohistorical, biocultural, and socioeconomic assessment data may provide important information about potential health risks; for example, a new Canadian may be at increased risk of exposure to tuberculosis depending on the country of origin.

Cultural assessment data inform a culturally safe physical assessment, by providing information that helps the nurse think critically about the political, social, and economic contexts of patients' lives and how inequities in power and access to resources for health influence the health of individuals (see Chapter 9; Browne & Varcoe, 2009). Applying a cultural safety lens will help the nurse avoid stereotyping patients on the basis of gender or ethnicity (see Chapter 9). Learn to recognize common biocultural variations of normal as well as disorders that may be more common in certain populations in the community. For example, infants of Aboriginal, Asian, or African descent may exhibit mongolian spots, which is a normal variation of hyperpigmentation seen in newborns (Jarvis et al., 2009). Canadians of Aboriginal, African, or South Asian ancestry may be more likely to exhibit the signs and symptoms of high blood pressure or diabetes (Jarvis et al., 2009). Providing culturally competent care potentially leads to greater patient satisfaction and improved clinical outcomes (Galanti, 2004).

Purposes of Physical Examination

An examination is designed to address the patient's needs. In an acutely ill patient, the nurse assesses only the involved body system(s). When a patient is having an asthmatic attack, the nurse initially assesses the pulmonary and cardiac systems. Then a more comprehensive examination about the patient's total health status is completed when the patient is physiologically more stable. Commonly, a complete physical examination is performed for routine screening to promote wellness behaviours and preventive health care measures, such as the routine annual medical exam. Additionally, a complete medical exam is often required to determine eligibility for extended health insurance, military service, a specialized driver's license, as a pre-employment medical exam for a new job, and with the admission process to hospital or long-term care facility.

A complete physical examination provides valuable information for all members of the patient's health care team. Thorough examination and documentation contribute to the following essential elements for comprehensive evidence-informed care:

- Gather baseline data about the patient's health status
- Supplement, confirm, or refute data obtained in the history
- Confirm and identify nursing diagnoses
- Make clinical judgements about a patient's changing health status and management
- Evaluate the outcomes of care

To assist in learning about the physical assessment of body systems, it is helpful to review anatomy. The Web site NurseONE contains an anatomy program, *Anatomy.tv*, that will assist in the identification and location of human anatomy. For example, you can use the program to identify the location of cranial nerves, which will be helpful for understanding

the function of each nerve and the muscles innervated by the nerve. Information on nursing student access to NurseONE can be found at the following link: <http://www.cnsa.ca/english/aboutus/faq/what-is-nurseone-and-how-do-i-register>. Then access NurseONE at <http://www.nurseone.ca/> and click the link to "Library," then click on "STAT!Ref," and then click on "Anatomy.tv."

Gathering a Health History

The main objective of interacting with patients is to find out what their concerns are and to help them find solutions. Pay close attention to a patient's concerns. Direct the interview and examination so that you can create a clear picture of the patient's condition. Collection of a health history and physical examination data requires patience and a dedication to thoroughness and detail. Conducting a successful interview and physical examination is based on several principles, relational practice being foremost (see Chapters 9 and 12). The interview allows for the formation of a partnership with the patient. Orient the interview to the patient, not to a disease. For example, a patient is not a "diabetic"; rather he or she is "a person who has diabetes." Make sure you know your own idiosyncrasies (e.g., wanting to be liked, fear of harming the patient or catching a disease) so you are able to prevent these feelings from affecting the therapeutic relationship you will develop with the patient.

Developing Nursing Diagnoses and a Care Plan

After gathering information about the patient's health from the health history, a subsequent physical assessment can reveal information that refutes, confirms, or supplements the history. Think critically about the information the patient provides, apply knowledge from previous clinical care, and methodically conduct the examination to create a clear picture of the patient's health status. For example, if a patient complains of back pain, ask the patient several questions to clarify the nature of the pain. During the examination, look carefully for the source of the pain (e.g., discomfort when changing position or a bruise across the patient's back) to rule out a variety of potential conditions (e.g., back strain, contusions, trauma, scoliosis). It is important to remember that one assessment finding (e.g., back pain) does not conclusively reveal the nature of an abnormality. A complete assessment is necessary to form a definitive nursing or medical diagnosis. Grouping significant findings into clusters of data assists in revealing actual or "risk for" nursing diagnoses (see Chapter 12). In addition, each abnormal finding suggests the need to gather additional information.

Information gathered during the initial history and physical assessment provides a baseline for the patient's functional abilities. This baseline is a record of findings identified when the patient was first assessed that can be used as a comparison for future assessment findings. Thus, the comprehensiveness and attention to detail in the documentation enable you and others to determine changes in a patient's condition during subsequent assessments.

The accuracy of the database allows for the development of an individualized nursing diagnosis (Table 31-1). Physical assessment findings determine the etiology of the diagnosis so that the selection of interventions is appropriate for the care plan. It is important to view physical assessment as an ongoing process, and thus the care plan changes with changes in the patient's condition. Ongoing monitoring of the patient's

progress and responses to therapies and treatments necessitate a review of the nursing diagnoses and plan of care as health conditions resolve or deteriorate, and when new health problems arise.

Managing Patient Problems

When caring for patients, the nurse assesses and performs a variety of interventions. Yet the nurse's success in giving care depends on the ability to recognize a change in status and to modify interventions so that patients gain the most desirable outcomes. Physical assessment skills allow nurses to judge the status of patients' health and direct the management of care. For example, the nurse inspects the skin during a routine bath and finds it excessively dry. The nurse does not use soap and applies body lotion to the skin. The nurse revises the written care plan so that other nurses know the type of skin care to provide and instructs the patient about skin care. Performing the mechanics of physical assessment is relatively simple. The more difficult challenge lies in using findings to make decisions.

Evaluating Nursing Care

Nurses demonstrate accountability for their nursing care through evaluating the results of nursing interventions. Physical assessment skills enhance the evaluation of nursing measures through monitoring physiological and behavioral outcomes of care. Nurses use physical assessment skills to assess a condition (e.g., palpation of the patient's pulse) and evaluate a patient's response to care (e.g., an evaluation of a patient's tolerance to an exercise plan). Accurate, detailed, objective documentation of measurements through physical assessment assists in determining whether the expected outcomes of care are met.

Skills of Physical Assessment

A comprehensive physical examination involves the use of five skills: inspection, palpation, percussion, auscultation, and olfaction.

Inspection

Inspection is the use of vision and hearing to distinguish normal from abnormal findings. It is important to know what to consider normal for patients of different age groups. You will need experience to recognize normal variations among patients. Inspection is a simple technique that can provide valuable clues about a patient's health status. The quality of an inspection depends on the nurse's willingness to spend time doing a thorough job. To inspect body parts accurately, follow these principles:

- Make sure adequate lighting is available.
- Position and expose body parts so all surfaces can be viewed.
- Inspect each area for size, shape, colour, symmetry, position, drainage, and abnormalities.
- When possible, compare each area inspected with the same area on the opposite side of the body.
- Use additional light (e.g., a penlight) to inspect body cavities.
- Do not hurry inspection. Pay attention to detail.

After inspection of a body part, findings sometimes indicate the need for further examination. Use palpation with or after visual inspection.

► **TABLE 31-1** Development of Individualized Nursing Diagnoses

Assessment Method	Findings	Patterns	Nursing Diagnosis
Inspection of skin	Skin along sacral area is intact. There is a 3 cm area of redness around coccyx; skin blanches on palpation.	There is pressure area around coccyx.	<i>Risk for impaired skin integrity</i>
Palpation of skin	There are no skin lesions. Skin is moist from diaphoresis. There is tenderness to palpation around sacral area. There is elastic skin turgor.	Skin moisture promotes maceration.	
Historical data	Patient suffered fractured left leg. Patient's mobility is reduced as a result of left leg traction.		

Palpation

Palpation involves the use of the hands to touch body parts to make sensitive assessments. Use palpation to examine all accessible parts of the body. For example, palpate the skin for temperature, moisture, texture, turgor, tenderness, and thickness. Palpate the abdomen for tenderness, **distension** (swelling), or masses. Use different parts of the hand to detect characteristics such as texture, temperature, and perception of movement (Table 31-2).

Before palpation, help the patient relax and be comfortable because muscle tension during palpation impairs effective assessment. To promote relaxation, have the patient take slow, deep breaths and place the arms along the side of the body. *Palpate tender areas last.* Be sure to ask the patient to point out the more sensitive areas. Watch the patient's facial expressions and body movements and note any nonverbal signs of discomfort.

Palpation requires warm hands, short fingernails, and a gentle approach. Perform palpation slowly, gently, and deliberately. Light, intermittent pressure is best when palpating; heavy, prolonged pressure causes a loss of sensitivity in the hand. To avoid injuring a patient, do not attempt deep palpation without clinical supervision. Caution is the rule. Use the most sensitive parts of the hand, the palmar surface of the fingers and finger pads, to determine position, texture, size, consistency, masses, fluid, and crepitus (Figure 31-1, A). Measure temperature using the dorsal surface or back of the hand (Figure 31-1, B). The ulnar surface of the hand and finger (Figure 31-1, C) is more sensitive to vibration. Measure position, consistency, and turgor by lightly grasping the body part with the fingertips (Figure 31-1, D).

Do not palpate without considering the patient's condition. For example, if the patient has a fractured rib, use extra care to locate the painful area. Do not palpate a vital artery with pressure that obstructs blood flow. Also consider the body area being palpated, as well as the reason for using palpation.

Percussion

Percussion involves tapping the body with the fingertips to produce a vibration that travels through body tissues. The character of the sound determines the location, size, and density of underlying structures to verify abnormalities assessed by palpation and auscultation. This vibration is transmitted through body tissues, and the character of the sound heard depends on the density of the underlying tissue. By knowing the way various densities influence sound, you locate organs or masses, map their boundaries, and determine their size. An abnormal sound suggests a mass or substance such as

► **TABLE 31-2** Examples of Characteristics Measured by Palpation

Area Examined	Criteria Measured	Portion of Hand to Use
Skin	Temperature	Dorsum of hand/fingers
	Moisture	Palmar surface
	Texture	
	Turgor and elasticity	Grasping with fingertips
Organs (e.g., liver and intestine)	Tenderness	Palmar surface/pads of fingertips
	Thickness	Palmar surface/pads of fingertips
	Size	Entire palmar surface of hand or palmar surface of fingers
	Shape	Palmar surface/pads of fingertips
Glands (e.g., thyroid and lymph)	Tenderness	Entire palmar surface of hand or palmar surface of fingers
	Absence of masses	
	Swelling	Pads of fingers
	Symmetry and mobility	Palmar surface/pads of fingertips
Blood vessels (e.g., carotid or femoral artery)	Pulse amplitude	Palmar surface/pads of fingertips
	Elasticity	
	Rate	
	Rhythm	
Thorax	Excursion	Palmar surface
	Tenderness	Finger pads/palmar surface of fingers
	Fremitus	Palmar or ulnar surface of entire hand

air or fluid within an organ or body cavity. The skill of percussion requires dexterity and is usually used by advanced practitioners.

Auscultation

Auscultation involves listening to sounds the body makes to detect variations from normal. You are able to hear some

Figure 31-1 A, Radial pulse is detected with the pads of fingertips, the most sensitive part of the hand. B, Dorsum of the hand detects temperature variations in skin. C, The bony part of the palm at the base of the fingers detects vibrations. D, Skin is grasped with the fingertips to assess turgor.

sounds without assistance but will need a stethoscope for most sounds.

First, learn the normal sounds created by the cardiovascular, respiratory, and gastrointestinal (GI) systems, such as the passage of blood through an artery. Recognize abnormal sounds after learning normal variations. Becoming more proficient in auscultation occurs by knowing the types of sounds each body structure makes and the location in which you hear the sounds best. Also, learn which areas do not normally emit sounds.

To auscultate correctly, the nurse needs to hear well, have a good stethoscope, and know how to use it properly. For those with a hearing disorder, use a stethoscope with greater sound amplification. Always place the stethoscope directly on the skin, because clothing obscures sound. Chapter 30 describes the parts of the stethoscope and its general use. The bell is best for low-pitched sounds, such as vascular and certain heart sounds, and the diaphragm is best for high-pitched sounds, such as bowel and lung sounds.

Be familiar with the stethoscope before attempting to use it. Practise using the stethoscope. Extraneous sounds created by movement of the tubing or chestpiece interfere with auscultation of body organ sounds. By deliberately producing these sounds, learn to recognize and disregard them during the actual examination.

Learn to recognize the following characteristics of sounds:

- Frequency, or the number of sound wave cycles generated per second by a vibrating object. The higher the frequency, the higher the pitch of a sound, and vice versa.
- Loudness, or the amplitude of a sound wave. Auscultated sounds are loud or soft.
- Quality, or sounds of similar frequency and loudness from different sources. Terms such as *blowing* or *gurgling* describe the quality of sound.
- Duration, or the length of time that sound vibrations last. The duration of sound is short, medium, or long. Layers of

soft tissue dampen the duration of sounds from deep internal organs.

Auscultation requires concentration and practice. Always consider the part of the body auscultated and the cause of the sound. For example, closure of the mitral valve causes the first heart sound. Learn where you hear the sounds best. You typically hear the first heart sound best when auscultated at the left fifth intercostal space along the midclavicular line. It is also important to learn the characteristics of normal sounds. The first heart sound has the quality of a loud “lub,” whereas the second sound is a “dub.” After understanding the cause and character of normal auscultated sounds, it becomes easier to recognize abnormal sounds and their origins.

Olfaction

While assessing a patient, become familiar with the nature and source of body odours (Table 31-3). Olfaction helps to detect abnormalities that you cannot recognize by any other means. For example, if a patient’s cast has a sweet, heavy, thick odour, this indicates an underlying infection. Findings from olfaction and other assessment skills should prompt the nurses to investigate the origin of the odour as it may indicate abnormalities.

Preparation for Examination

Proper preparation of the environment, equipment, and patient ensures a smooth physical examination with few interruptions. A disorganized approach when preparing for a physical examination will cause errors and incomplete findings.

Infection Control

During an examination, some patients will present with open skin lesions or weeping wounds. Use standard precautions throughout the examination (see Chapter 32) as appropriate. It is necessary to wear gloves during palpation and percussion to reduce contact with microorganisms. If a patient has excessive

► **TABLE 31-3** Assessment of Characteristic Odours

Odour	Site or Source	Potential Causes
Alcohol	Oral cavity	Ingestion of alcohol, diabetes
Ammonia	Urine	Urinary tract infection, renal failure
Body odour	Skin, particularly in areas where body parts rub together (e.g., underarms and under breasts)	Poor hygiene, excess perspiration (hyperhidrosis), foul-smelling perspiration (bromhidrosis)
	Wound site	Wound abscess
	Vomitus	Abdominal irritation, contaminated food
Feces	Vomitus/oral cavity (fecal odour)	Bowel obstruction
	Rectal area	Fecal incontinence
Foul-smelling stools in infant	Stool	Malabsorption syndrome
Halitosis	Oral cavity	Poor dental and oral hygiene, gum disease
Sweet, fruity ketones	Oral cavity	Diabetic acidosis
Stale urine	Skin	Uremic acidosis
Sweet, heavy, thick odour	Draining wound	<i>Pseudomonas</i> (bacterial) infection
Musty odour	Casted body part	Infection inside cast
Fetid, sweet odour	Tracheostomy or mucous secretions	Infection of bronchial tree (<i>Pseudomonas</i> bacteria)

drainage or risk of spray from a wound, wear a gown and other personal protective equipment as needed. Always wash hands before initiating and after completing a physical assessment.

Environment

A physical examination requires privacy. A well-equipped examination room is preferable, but often the examination occurs in the patient's room. In the home, you will often perform an examination in the patient's bedroom. Any examination room needs to be well equipped for all necessary procedures. Adequate lighting is necessary for proper illumination of body parts. Ideally, an examination room is soundproof, so patients feel comfortable discussing their conditions. Be sure to eliminate sources of noise, take precautions to prevent interruptions from others, and make sure the room is warm enough to maintain comfort.

Sometimes it is difficult to perform a complete examination when patients are in beds or on stretchers. Special examination tables make patients easily accessible and help them assume special positions. Carefully assist patients so that they do not fall while getting on and off the table. Do not leave a confused, combative, or uncooperative patient unsupervised on an examination table.

Examination tables are often hard and uncomfortable. When the patient lies supine, raise the head of the table about 30 degrees. Also give the patient a small pillow to use. When

Figure 31-2 Equipment used during a physical examination.

examining a patient in bed, raise the bed to reach the patient's body parts more easily. Remember to use proper body mechanics to ensure your physical safety while performing an exam.

Equipment

Perform hand hygiene thoroughly before equipment preparation and the examination. Set up equipment so it is readily available and arranged in order for easy use (Figure 31-2). Keep equipment as warm as appropriate. Rub the diaphragm of the stethoscope briskly between the hands before applying it to the skin. If assisting with a vaginal exam, run warm water over the vaginal speculum just before using. The ophthalmoscope and otoscope require good batteries and light bulbs. Check all equipment to ensure that it functions properly. Box 31-1 lists typical physical assessment equipment used to perform a complete medical exam.

Physical Preparation of the Patient

The patient's physical comfort is vital for an accurate examination. Before starting, ask if the patient needs to use the restroom. An empty bladder and bowel facilitate examination of the abdomen, genitalia, and rectum. Collection of urine or fecal specimens occurs at this time if needed. Be sure to explain the proper method for collecting specimens, and make sure to label each specimen properly.

Physical preparation involves being sure the patient is dressed and draped properly. The patient in the hospital will likely be wearing only a simple gown. An outpatient will have to undress and wear a light cover gown. If the examination is limited to certain body systems, it is not always necessary for the patient to undress completely. Provide the patient privacy and plenty of time during undressing. Walking into the room as the patient undresses causes embarrassment. Drapes and gowns are made of linen or disposable paper. After patients have undressed and put on a gown, they sit or lie down on the examination table with the drape over the lap or lower trunk. Make sure the patient stays warm by eliminating drafts, controlling room temperature, and providing warm blankets. Routinely ask if the patient is comfortable.

► BOX 31-1

Equipment and Supplies for Physical Assessment

- Cervical brush or broom devices (if needed)
- Cotton applicators
- Disposable pad/paper towels
- Drapes
- Eye chart (e.g., Snellen chart)
- Flashlight and spotlight
- Forms (e.g., physical, laboratory)
- Gloves (sterile and clean)
- Gown for patient
- Ophthalmoscope
- Otoscope
- Papanicolaou (Pap) liquid prep (if needed)
- Percussion (reflex) hammer
- Pulse oximeter
- Ruler
- Scale with height measurement rod
- Specimen containers, slides, wooden or plastic spatula, and cytological fixative (if needed)
- Sphygmomanometer and cuff
- Sterile swabs
- Stethoscope
- Tape measure
- Thermometer
- Tissues
- Tongue depressors
- Tuning fork
- Vaginal speculum (if needed)
- Water-soluble lubricant
- Wristwatch with second hand or digital display

Positioning. During the examination ask the patient to assume proper positions so that body parts are accessible and the patient stays comfortable. Table 31-4 lists the preferred positions for each part of the examination and contains figures illustrating these positions. Patients' abilities to assume positions will depend on their physical strength, mobility, ease of breathing, age, and degree of wellness. Explain the positions, and assist patients in assuming them. Adjust the drapes so that the area examined is accessible, making sure not to unnecessarily expose a body part. A patient may assume more than one position. To decrease the number of times the patient changes positions, organize the examination so that you perform all techniques requiring a sitting position first, then perform those that require a supine position next, and so forth. Be sure to use extra care when positioning older adults, because they are more prone to having disabilities and limitation.

Psychological Preparation of the Patient

Many patients find an examination stressful or tiring, or they experience anxiety about possible findings. A thorough explanation of the purpose and steps of each assessment lets patients know what to expect and what to do so that they can cooperate. Keep explanations simple and in understandable terms. Help patients to feel free to ask questions and mention any discomfort. As you examine each body system, give a more detailed explanation. Convey an open, professional approach while remaining relaxed. A still, formal demeanour will inhibit the patient's ability to communicate, but a style that is too casual will fail to assure the patient (Jarvis et al., 2009).

When the patient and nurse are of opposite gender, it helps to have a third person of the patient's gender in the room. The presence of a third person assures the patient that the examiner will behave ethically. This person is also a witness to the examiner's conduct and the patient's.

During the examination, watch the patient's emotional responses. Observe whether the patient's facial expression shows fear or concern and if body movements show anxiety. Remain calm, and explain each step clearly. It is sometimes necessary to stop the examination and ask how the patient feels. Do not force the patient to continue. Postponing the examination is advantageous because the findings may be more accurate when the patient can cooperate and relax. If the patient's fears result from misconceptions, clarify the purpose of the examination and how you will perform it.

Assessment of Age Groups

It is necessary to use different interview styles and approaches to physical examination for patients of different age groups. When assessing children, be sensitive and anticipate the child's reaction to the examination as a strange and unfamiliar experience. Routine pediatric examinations focus on health promotion and illness prevention, particularly for the care of well children who have no serious health problems (Hockenberry & Wilson, 2007). This examination focuses on growth and development, sensory screening, dental examination, and behavioural assessment. Children who are chronically ill or disabled, foster children, or adopted children sometimes require additional examination visits. When examining children, the following tips assist in data collection:

- Gather all or part of the histories on infants and children from parents or guardians.
- Perform the examination in a nonthreatening area; provide time for play to become acquainted.
- Because parents sometimes think the examiner is testing them, offer support during the examination and do not pass judgement.
- Call children by their first name, and address the parents as "Mr.," "Mrs.," or "Ms.," rather than by their first names.
- Use open-ended questions to allow parents to share more information and describe more of the children's problems. This also allows observation of parent-child interactions. Interview older children, who often provide details about their health history and severity of symptoms.
- Treat adolescents as adults and individuals because they tend to respond best when treated as such.
- Remember that adolescents have the right to confidentiality. After talking with parents about historical information, make an opportunity to speak alone with adolescents.

Pediatric (Box 31-2) and geriatric (Box 31-3) assessments tools are used to document and evaluate changes in health status. In children the Rourke assists in the examination of normal growth and development in children. In the geriatric population, a functional assessment, evaluation of activities of daily living, might determine the need for assistance in the home.

Organization of the Examination

The physical examination is made up of individual assessments for each body system. Patients with specific symptoms or needs require only portions of an examination. A patient

► **TABLE 31-4** Positions for Examination

Position	Areas Assessed	Rationale	Limitations
Sitting 	Head and neck, back, posterior thorax and lungs, anterior thorax and lungs, breasts, axillae, heart, vital signs, and upper extremities	Sitting upright provides full expansion of lungs and provides better visualization of symmetry of upper body parts.	Physically weakened patient is sometimes unable to sit. Use supine position with head of bed elevated instead.
Supine 	Head and neck, anterior thorax and lungs, breasts, axillae, heart, abdomen, extremities, pulses	This is most normally relaxed position. It provides easy access to pulse sites.	If patient becomes short of breath easily, raise the head of bed.
Dorsal recumbent 	Head and neck, anterior thorax and lungs, breasts, axillae, heart, abdomen	Position is for abdominal assessment because it promotes relaxation of abdominal muscles.	Patients with painful disorders are more comfortable with knees flexed.
Lithotomy* 	Female genitalia and genital tract	This position provides maximal exposure of genitalia and facilitates insertion of vaginal speculum.	Lithotomy position is embarrassing and uncomfortable, so examiner minimizes time that patient spends in it. Keep patient well draped.
Sims' 	Rectum and vagina	Flexion of hip and knee improves exposure of rectal area.	Joint deformities hinder patient's ability to bend hip and knee.
Prone 	Musculoskeletal system	This position is only for assessing extension of hip joint, skin, buttocks.	Patients with respiratory difficulties do not tolerate this position well.
Lateral recumbent 	Heart	This position aids in detecting murmurs.	Patients with respiratory difficulties do not tolerate this position well.
Knee-chest* 	Rectum	This position provides maximal exposure of rectal area.	This position is embarrassing and uncomfortable.

*Some patients with arthritis or other joint deformities are unable to assume this position.

► **BOX 31-2** Developmental Assessment of Infants and Children

A good Canadian resource for the assessment of children is the Rourke Baby Record (Rourke et al., 2001). This tool provides information about growth and developmental milestones for children from birth to five years of age. The tool combines helpful information on nutrition, child safety, and the childhood immunization schedule. A Rourke Baby Record can be downloaded free from the Web site <http://www.rourkebabyrecord.ca/index.html>. Information about the tool development and associated evidence is also accessible from this Web site.

► **BOX 31-3** Geriatric Assessment Tools

A number of assessment tools are used with older adults to assess functional independence. Functional independence is the ability to perform basic personal care and activities and support independent living. Most often, functional assessment tools are used to assess older adults; however, younger individuals with spinal cord injuries or head injuries can be assessed using these tools as well.

Many screening tools are available that help nurses to assess their older adult patients' independence in the home, or their level of functioning on return home from hospital. Nurses who work with older adults should increase their knowledge about functional assessment tools (Ebersole et al., 2007). The Katz Index (Katz et al., 1963), although published a number of years ago, provides a simple screening evaluation of activities of daily living. Access to this tool is free from many sources online.

who comes to a clinic with symptoms of a severe chest cold will not routinely require a neurological assessment. A patient entering the emergency department with an acute illness requires assessment of the body systems most at risk for being abnormal. When a patient is admitted to the hospital, a

complete examination is performed. A patient who is receiving a routine health promotion examination undergoes specific preventive screenings, depending on the patient's age or health risk (Table 31-5). Patients with specific symptoms or needs often require only portions of an examination. Use

► **TABLE 31-5** Recommended Preventive Screenings

Screening Measure	All Ages	Ages 20-39	Ages 40-49	Ages 50-65	Ages 65+
Breast cancer		Self-exam and annual exam with health care practitioner	Self-exam and biannual exam with health care practitioner	Self-exam, biannual exam with health care practitioner Biannual mammography	Self-exam, biannual exam with health care practitioner Biannual mammography to age 70
Colon/rectal cancer				Biannual fecal occult blood	
Diabetes	Based on evidence suggesting risk	Based on evidence suggesting risk	Fasting plasma glucose every 3 years over the age of 40	Fasting plasma glucose every 3 years	Fasting plasma glucose every 3 years

Oral cavity/pharyngeal disorders	Dental exam every 6 months				
Ovarian cancer		At age 18 years or on becoming sexually active	Annually	Annually	Annually
Prostate cancer				Men who have at least a 10-year life expectancy need to have a digital rectal examination (DRE) and prostate-specific antigen (PSA) blood test annually. Men at higher risk require earlier screening.	Men who have at least a 10-year life expectancy need to have a digital rectal examination (DRE) and prostate-specific antigen (PSA) blood test annually. Men at higher risk require earlier screening.
Skin cancer	Routine self-exam and annual health care practitioner exam				
Testicular cancer	Males age 15+ years and regular testicular self-examination (TSE)				
Uterine cancer		Annual health care practitioner exam at age 18 or upon becoming sexually active	Annual health care practitioner exam	Annual health care practitioner exam	Annual health care practitioner exam

Continued

► TABLE 31-5 Recommended Preventive Screenings—cont'd

Screening Measure	All Ages	Ages 20-39	Ages 40-49	Ages 50-65	Ages 65+
Cervical cancer		Screening with pelvic examination by health care provider plus an annual Papanicolaou (Pap) test begins 3 years after having vaginal intercourse, but not later than age 21. Frequency of 1-3 years, depending on provincial screening guidelines.	Papanicolaou (Pap) test frequency of 1-3 years, depending on provincial screening guidelines.	Papanicolaou (Pap) test frequency of 1-3 years, depending on provincial screening guidelines.	Papanicolaou (Pap) test frequency of 1-3 years, depending on provincial screening guidelines.
Endometrial cancer		Annual health care practitioner exam at age 18+, or on becoming sexually active.	Endometrial biopsy at age 35 for high-risk patients (those with or at risk for hereditary nonpolyposis colon cancer [HNPCC])	At menopause, women of average and high risk need to be informed about signs and symptoms to report.

judgement to ensure that an examination is relevant and includes the correct observations.

The performance of a complete health assessment follows the format of the nursing history (see Chapter 12). Obtain information from the history to focus attention on specific parts of the examination. Findings from the history generally reveal a pattern of related signs and symptoms. The physical examination supplements information from the history to confirm or refute the data.

Be systematic and well organized about the examination so you do not miss important assessments. A head-to-toe approach includes all body systems and helps to anticipate each step. In an adult, begin by assessing the head and neck structures, including hair and skin, and progressing methodically down the body to incorporate all body systems. The following tips help keep an examination well organized:

- Compare both sides of the body for symmetry. A degree of asymmetry is normal (e.g., the biceps muscles in the dominant arm are sometimes more developed than the same muscles in the nondominant arm).
- If a patient is seriously ill, first assess the systems of the body more at risk for being abnormal. For example, a patient with chest pain first undergoes a cardiovascular assessment.
- If a patient becomes fatigued, offer rest periods between assessments.
- Perform painful procedures near the end of the examination.
- Record assessments in specific terms on a physical assessment form or in the nurses' notes.

- Use common and accepted medical abbreviations to keep notes brief and concise.
- Record quick notes during the examination to avoid keeping the patient waiting. Complete any observations at the end of the examination.
- A physical assessment form allows you to record information in the same sequence as you gather it.

General Survey

Assessment begins when first meeting the patient. Determine the patient's reason for seeking health care. Initial data from the general survey begins with a review of the patient's primary health problems. Make mental notes of the patient's behaviour and appearance. Begin the examination with a general survey. The survey provides information about characteristics of an illness, a patient's hygiene and body image, emotional state, recent changes in weight, and developmental status. If there are abnormalities or problems, closely assess the affected body system later.

General Appearance and Behaviour

Assess appearance and behaviour while preparing the patient for the examination. The review of general appearance and behaviour includes the following:

- **Age and gender:** A person's gender and age affect the type of examination performed and the manner in which you make assessments. Physical characteristics offer clues that help guide your examination. Certain conditions are more likely to affect individuals of a specific gender or who have certain

physical characteristics; for example, breast cancer is more common in women than men, and the incidence of skin cancer is higher in individuals who have fair complexions.

- **Signs of distress:** There are sometimes obvious signs or symptoms indicating pain (grimacing, splinting painful area) or difficulty in breathing (shortness of breath, sternal retractions) or anxiety. These signs establish priorities regarding what to examine first.
- **Body type:** Observe if a patient appears trim and muscular, obese, or excessively thin. Body type reflects the level of health, age, and lifestyle.
- **Posture:** Normal standing posture is an upright stance with parallel alignment of the hips and shoulders. Normal sitting posture involves some degree of rounding of the shoulders. Observe whether the patient has a slumped, erect, or bent posture. Posture often reflects mood or pain. Many older adults assume a stooped, forward-bent posture, with the hips and knees somewhat flexed and the arms bent at the elbows, raising the level of the arms.
- **Gait:** Observe the patient walking into the room or at the bedside (if the patient is ambulatory). Note whether movements are coordinated or uncoordinated. A person normally walks with the arms swinging freely at the sides, with the head and face leading the body.
- **Body movements:** Observe whether movements are purposeful, and note if there are any tremors involving the extremities. Determine if any body parts are immobile.
- **Hygiene and grooming:** Note the patient's level of cleanliness by observing the appearance of the hair, skin, and fingernails. Note if the patient's clothes are clean. Grooming depends on the activities being performed just before the examination, as well as the patient's occupation. Also note the amount and type of cosmetics used.
- **Dress:** Culture, lifestyle, socioeconomic level, and personal preference affect the type of clothes worn. Note if the type of clothing worn is appropriate for the temperature and weather conditions. Depressed or mentally ill individuals are often unable to choose proper clothing. An older adult tends to wear extra clothing because of the sensitivity to cold.
- **Body odour:** An unpleasant body odour often results from physical exercise, poor hygiene, or certain disease states.
- **Affect and mood:** Affect is a person's feelings as they appear to others. Patients express mood or emotional state verbally and nonverbally. Note if verbal expressions match nonverbal behaviour. Observe if mood is appropriate for the situation. Observe facial expressions while asking questions.
- **Speech:** Normal speech is understandable and moderately paced. It shows an association with the person's thoughts. Note if the patient talks rapidly or slowly. Emotions or neurological impairment sometimes cause an abnormal pace. Observe whether the patient speaks in a normal tone with clear inflection of words.
- **Patient abuse:** Abuse of children, women, and older adults is a growing health problem. Obvious physical injury or neglect are signs of possible abuse (e.g., evidence of malnutrition or presence of bruising on the extremities or trunk). Assess for the patient's fear of the spouse or partner, caregiver, parent, or adult child. Note if the partner or caregiver has a history of violence, alcoholism, or drug abuse. Is the person unemployed, ill, or frustrated in caring for the patient? Most provinces mandate a report to a social service agency if you suspect abuse or neglect (Box 31-4). When

► BOX 31-4 Clinical Indicators of Abuse

Physical Findings

Child Sexual Abuse

Vaginal or penile discharge
Blood on underclothing
Pain, itching, or unusual odour in genital area
Genital injuries
Difficulty sitting or walking
Pain while urinating; recurrent urinary tract infections
Foreign bodies in rectum, urethra, or vagina
Sexually transmitted infections
Pregnancy in young adolescent

Behavioural Findings

Problem in sleeping or eating
Fear of certain people or places
Play activities re-create the abuse situation
Regressed behaviour
Sexual acting out
Knowledge of explicit sexual matters
Preoccupation with others' or own genitals
Profound and rapid personality changes
Rapidly declining school performance
Poor relationship with peers

Domestic Abuse

Injuries and trauma are inconsistent with reported cause
Multiple injuries involving head, face, neck, breasts, abdomen, and genitalia (black eyes, orbital fractures, broken nose, fractured skull, lip lacerations, broken teeth, strangulation marks)
X-ray films show old and new fractures in different stages of healing
Abrasions, lacerations, bruises/welts
Burns
Human bites

Attempted suicide
Eating or sleeping disorders
Anxiety
Panic attacks
Pattern of substance abuse (follows physical abuse)
Low self-esteem
Depression
Sense of helplessness
Guilt
Increased forgetfulness
Stress-related complaints (headache, anxiety)

Older Adult Abuse

Injuries and trauma are inconsistent with reported cause (cigarette burn, scratch, bruise, or bite)
Hematomas
Bruises at various stages of resolution
Bruises, chafing, excoriation on wrist or legs (restraints)
Burns
Fractures inconsistent with cause described
Dried blood

Dependent on caregiver
Physically and/or cognitively impaired
Combative
Wandering
Verbally aggressive
Minimal social support
Prolonged interval between injury and medical treatment

St. Louis, MO: Mosby.

you suspect abuse, interview the patient in private. It is difficult to detect abuse, because victims often will not complain or report that they are in an abusive situation (Witte, 2009). Patients are more likely to reveal any problems when the suspected abuser is absent from the room (Witte, 2009).

► BOX 31-5

Red Flags for Suspicion of Substance Abuse

- Patients who frequently miss appointments
- Patients who frequently request written excuses for absence from work
- Patients who have chief complaints of insomnia, “bad nerves,” or pain that does not fit a particular pattern
- Patients who often report lost prescriptions (e.g., tranquilizers or pain medications) or ask for frequent refills
- Patients who make frequent emergency department visits
- Patients who have a history of changing health care providers or who bring in medication bottles prescribed by several different providers
- Patients with a history of gastrointestinal bleeds, peptic ulcers, pancreatitis, cellulitis, or frequent pulmonary infections
- Patients with frequent sexually transmitted infections (STIs), complicated pregnancies, multiple abortions, or sexual dysfunction
- Patients who complain of chest pains or palpitations or who have a history of admissions to rule out myocardial infarctions
- Patients who give histories of activities that place them at risk for human immunodeficiency virus (HIV) infections (multiple partners, multiple rapes)
- Patients with a family history of addiction; history of childhood sexual, physical, or emotional abuse; or social and financial or marital problems

If two or more of the CAGE questions are positive, strongly suspect substance abuse and consider how to motivate the patient to seek treatment.

Data from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders (DSM-IV-TR)*. Washington, DC: Author; Reis, R. K., Fiellin, D. A., Miller, S. C., & Saitz, R. (Eds.). (2009). *Principles of addiction medicine: The essentials* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins; and Widlitz, M., & Marin, D. (2002). Substance abuse in older adults: An overview. *Geriatrics*, 57(12), 29–34.

safety alert The risk for further abuse is high once the victim has reported the abuse or tries to leave the abusive situation. Provide counselling options for these individuals.

- **Substance abuse:** Substance abuse affects all socioeconomic groups. A single visit to a clinic does not always reveal the problem. Several visits often reveal behaviours that you can confirm with a well-focused history and physical examination. Approach the patient in a caring and nonjudgemental way, because issues of substance abuse involve both emotional and lifestyle issues. Box 31-5 lists patients to suspect for substance abuse. When you suspect substance abuse, ask the following CAGE questions (CAGE is an acronym for the following):
 - Have you ever felt the need to **Cut down** on your drinking or drug use?
 - Have people **Annoyed** you by criticizing your drinking or drug use?
 - Have you ever felt bad or **Guilty** about your drinking or drug use?
 - Have you ever used or had a drink first thing in the morning as an **Eye-opener** to steady your nerves or feel normal?

Vital Signs

Assessment of vital signs (see Chapter 30) is the first part of the physical examination. Positioning or moving the patient during the examination interferes with obtaining accurate values. You can also measure specific vital signs during assessment of individual body systems.

Height and Weight

Height and weight reflect a person's general level of health. Weight is a routine measure during health screenings and visits to physicians' offices or clinics. Both measures are routine when patients are admitted to a health care setting. Health care providers measure an infant or child's height and weight to assess growth and development. In older adults, height and weight coupled with a nutritional assessment determine the cause of and treatment for chronic disease or help to identify the older adult who has difficulty with feeding and other functional activities. Be sure to look for overall trends in height and weight as changes can be indicative of health problems.

A patient's weight will normally vary daily because of fluid loss or retention. A downward trend in a frail older adult indicates serious reduction in nutritional reserves. Assessments screen for abnormal weight changes. The nursing history helps to focus on possible causes for a change in weight (Table 31-6). First ask the patient his or her current height and weight. Also assess weight gains or losses. A weight gain of 2.3 kg (5 lb) in a day indicates fluid retention problems. If the patient has lost more than 5% of body weight in a month or 10% in six months, the loss is significant.

Body mass index (BMI) tables help reveal the normal expected weight range for a patient at a given height (Figure 31-3). The body mass index uses waist circumference of adults to measure the health risk associated with obesity. A patient's waist is measured midway between the costal margin and the iliac crest. Measurement should be taken to the nearest 0.5 cm at the end of expiration. The tape measure should fit snugly but should not compress soft tissue. Locating the intersection of the patient's height and weight on the BMI table will indicate the patient's BMI. The risk for health based on this value can be assessed using the BMI categories. Patients at high risk should be encouraged to seek the care of a health care practitioner for weight loss, dietary changes, and exercise programs.

You need to weigh patients at the same time of day, on the same scale, and in the same clothes to allow an objective comparison of subsequent weights. Accuracy of weight measurement is important because health care providers will base medical and nursing decisions (e.g., drug dosage determinations, lifting, and positioning) on changes. Patients capable of bearing their own weight use a standing scale. Calibrate a standard platform scale by moving the large and small weights to zero. Make the balance beam level and steady by adjusting the calibrating knob. The patient stands on the scale platform and remains still. Move the largest weight to the 22.5 kg increment under the patient's weight. Then adjust the smaller weight to balance the scale at the nearest 0.1 kg (Jarvis et al., 2009). Electronic scales automatically display the weight within seconds. Electronic scales are automatically calibrated each time they are used.

Stretcher and chair scales are available for patients unable to bear weight. After you transfer the patient to the scale, a hydraulic device lifts the patient above the bed and measures the weight on a balance beam or digital display. Use caution when transferring patients to and from the scales.

▶ TABLE 31-6

Nursing History for Weight Assessment

Assessment Category

Ask about total weight lost or gained; compare with usual weight; note time period for loss (e.g., gradual, sudden, desired, or undesired).

If weight loss desired, ask about eating habits, diet plan followed, food preparation, calorie intake, appetite, exercise pattern, support group participation, weight goal.

If weight loss undesired, ask about anorexia, vomiting, diarrhea, thirst, frequent urination, and change in lifestyle, activity, and stress levels.

Assess if patient has noted changes in social aspects of eating: more meals in restaurants, rushing to eat meals, stress at work, or skipping meals.

Assess if patient takes chemotherapy, diuretics, insulin, fluoxetine, prescription and nonprescription appetite suppressants, laxatives, oral hypoglycemics, and herbal supplements (weight loss); steroids, oral contraceptives, antidepressants, insulin (weight gain).

Assess for preoccupation with body weight or body shape such as fasting, never feeling thin enough, unusually strict caloric intake or restrictions, laxative abuse, induced vomiting, amenorrhea, excessive exercise, alcohol intake.

Rationale

Determines severity of problem and reveals if weight change is related to disease process, change in eating pattern, or pregnancy.

Helps to determine appropriateness of diet plan followed.

Focuses on problems that cause weight loss (e.g., gastrointestinal problems).

Lifestyle changes sometimes contribute to weight changes.

Weight gain or loss is a side effect of these medications.

Indicates an eating disorder.

Always weigh infants in baskets or on platform scales. Remove the infant's clothing, and weigh the infant in dry, disposable diapers. Adjust the measurement later for the weight of the diaper, ensuring an accurate reading. Keep the room warm to prevent chills. A light cloth or paper placed on the scale's surface prevents cross-infection from urine or feces. When placing infants in baskets or on platforms, hold a hand lightly above to prevent accidental falls. You measure weight in grams.

To measure the height of weight-bearing patients, have them remove their shoes. Place a paper towel on the scale platform or floor so the patient's feet remain clean. A measuring stick or tape is attached vertically to the weight scales or wall. Have the patient stand erect. The platform scale has a metal rod attached to the back of the scale; this swings out and over the crown of the head. You can also place a measuring stick or flat book on the head when a scale is unavailable. With the rod or stick placed level horizontally at a 90-degree angle to the measuring stick, measure the patient's height in centimetres.

A

Waist circumference	BMI category		
	Normal 18.5–24.9 kg/m ²	Overweight 25–29.9 kg/m ²	Obese class I 30–34.9 kg/m ²
Men: < 102 cm Women: < 88 cm	Least risk	Increased risk	High risk
Men: ≥ 102 cm Women: ≥ 88 cm	Increased risk	High risk	Very high risk

B

Figure 31-3 Height and weight measures: Weights for people over 18 years (excluding pregnant or lactating women)

- Weight and height are required to measure a person's BMI, which is calculated by dividing weight (kg) by height squared (m²).
- Weight is measured with the patient wearing light clothing and no footwear and is recorded to the nearest 0.2 kg.
- Height is measured with the person wearing no shoes, standing in an erect position, looking straight ahead with feet together and heels against a wall or measuring board. A horizontal bar or other similar device should be lowered so that it rests flat on top of the person's head. Height is recorded to the nearest 0.5 cm.
- For a quick determination of BMI, use a straight-edge to help locate the point on the chart below where height and weight intersect. Read the number on the dashed line closest to this point. For example, a person who weighs 69 kg and is 173 cm tall has a BMI of about 23.

NOTE: The BMI cannot be used to distinguish between increased body weight due to adiposity or fluid retention (e.g., peripheral edema), although this distinction should be apparent clinically. The BMI may have limitations in people who are very muscular or very lean, in those who are very tall or very short, in people with long limb lengths relative to trunk size (e.g., those with Marfan syndrome) and in people with short limb lengths relative to trunk size (e.g., those with achondroplasia). **Source:** A, Health Canada (2003). *Canadian guidelines for body weight classification in adults* (Catalogue no. H49-179/2003E; p. 37). Ottawa: Health Canada. Retrieved from http://www.hc-sc.gc.ca/fn-an/nutrition/weights-poids/guide-ld-adult/cg_quick_ref-ldc_rapide_ref-eng.php; and B, Douketis, J. D., Paradis, G., Keller, H., & Martineau, C. (2005). Canadian guidelines for body weight classification in adults: Application in clinical practice to screen for overweight and obesity and assess disease risk. *Canadian Medical Association Journal*, 172(8), 995–998.

Figure 31-4 Measurement of infant length. **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 103). St Louis, MO: Mosby. Courtesy seca GmbH, Hamburg, Germany.

Remove the shoes of a non-weight-bearing patient, and position the patient (such as an infant) supine on a firm surface. Portable devices are available that provide a reliable means to measure height. Place the infant on the device, having the parent hold the infant's head against the headboard. With the infant's legs straight at the knees, place the footboard against the bottom of the infant's feet (Figure 31-4). Record the infant's length to the nearest 0.5 cm.

The Integumentary System: Skin, Hair, and Nails

The **integument** consists of the skin, hair, scalp, and nails. Developing a routine approach to physical assessment helps to ensure the completeness of your exam. For the purposes of presentation in this chapter, the approach to patient assessment begins with the inspection of all skin surfaces. Alternatively, as your assessment skills develop, you may choose to assess the skin gradually while examining other body systems (e.g., inspecting the skin of the torso while assessing the respiratory, cardiovascular, and abdominal systems). Use the skills of inspection, palpation, and olfaction to assess the integument's function and integrity.

Skin

Assessment of the skin reveals changes in oxygenation, circulation, nutrition, local tissue damage, and hydration. In a hospital setting, the majority of patients are older adults, debilitated patients, or young but seriously ill patients. There are significant risks for skin lesions resulting from trauma to the skin during administration of care, from exposure to pressure during immobilization, or from reaction to various medications used in treatment. Patients at high risk are the neurologically impaired, chronically ill, and orthopedic patients. Others at risk are patients with diminished mental status, poor tissue oxygenation, low cardiac output, or inadequate nutrition. In nursing homes and extended care facilities, patients are often at risk for many of the same problems, depending on their level of mobility and the presence of chronic illness. Routinely assess the skin to look for primary or initial lesions that

* BOX 31-6 PATIENT TEACHING

Skin Assessment

Objectives

- Patient will perform a monthly self-examination of the skin.
- Patient will identify factors that increase the risk of skin cancer.
- Patient will follow hygiene practices aimed at maintaining skin integrity.

Teaching Strategies

- Instruct patient to conduct a complete monthly self-examination of the skin, noting moles, blemishes, and birthmarks. Tell patient to inspect all skin surfaces. Cancerous melanomas start as small, molelike growths that increase in size, change colour, become ulcerated, and bleed (see Box 31-10, p. 557).
- Tell patient to report to a physician or health care provider any change in skin lesions or a sore that does not heal.
- Instruct patient to report to a physician any lesion that bleeds or fails to heal. Especially instruct older adults, who tend to have delayed wound healing.
- To treat excessively dry skin, tell patient to avoid hot water, harsh soaps, and drying agents such as rubbing alcohol. Use a superfatted (Dove) soap, and pat rather than rub the skin after bathing.
- Apply moisturizers (mineral oil) to the skin regularly to reduce itching and drying, and wear cotton clothing (Marks & Miller, 2006).

Evaluation

- Observe patient performing a skin assessment.
- Have the patient describe signs of skin cancer and measures to take to prevent skin cancer.
- Ask the patient to describe methods for keeping the skin lubricated and supple.

develop. Without proper care, primary lesions can deteriorate to become secondary lesions that require more extensive nursing care. The development of a pressure ulcer, for example, will lengthen a hospital stay unless you prevent or discover it early and treat it properly (see Chapter 46).

It was estimated that approximately 5300 new cases of **melanoma**, an aggressive form of skin cancer, would be diagnosed in 2010 (Canadian Cancer Society [CCS] Steering Committee, 2010). In addition, health care providers could expect to see approximately 75,000 new cases of the highly curable basal cell and squamous cell cancers (CCS Steering Committee, 2010). Cutaneous malignancies are the most common neoplasms seen in patients. Incorporate performing a thorough skin assessment on all patients with educating them about self-examination (Box 31-6).

The condition of the patient's skin reveals the need for nursing intervention. Use assessment findings to determine the type of hygiene measures required to maintain integrity of the integument (see Chapter 37). Adequate nutrition and hydration become goals of therapy if you identify an alteration in the integument's status (see Chapter 42).

You need adequate lighting to accurately observe a patient's skin. The recommended choice is natural or halogen lighting. For detecting skin changes in the dark-skinned patient, sunlight is the best choice (Marks & Miller, 2006). Room

temperature also affects skin assessment. A room that is too warm causes **superficial vasodilation**, resulting in an increased redness of the skin. A cool environment causes the sensitive patient to develop **cyanosis** (bluish discoloration) around the lips and nail beds.

Use disposable gloves for palpation if open, moist, or draining lesions are present. Although you inspect each part of the body during an examination, it is helpful to make a brief but careful overall visual sweep of the entire body. This provides a good idea of the distribution and extent of any lesions, as well as the overall symmetry of skin colour. Because you need to inspect all skin surfaces, the patient will assume several positions. Table 31-7 outlines the nursing history for skin

assessment. If you notice abnormalities during an examination, palpate the involved areas. Skin odours are usually apparent in the folds of the skin, such as the axillae or under the female patient's breasts. Figure 31-5 illustrates a normal cross-section of the skin.

Colour. Skin colour varies from body part to body part and from person to person. Despite individual variations, skin colour is usually uniform over the body. Table 31-8 lists common variations. Normal skin **pigmentation** ranges in tone from ivory or light pink to ruddy pink in light skin and from light to deep brown or olive in dark skin. In older adults, pigmentation increases unevenly, causing discoloured skin. While inspecting the skin, be aware that cosmetics or tanning agents sometimes mask colour.

The assessment of colour first involves areas of the skin not exposed to the sun, such as the palms of the hands. Note if the skin is unusually pale or dark. Areas exposed to the sun, such as the face and arms, will be darker. It is more difficult to note changes such as pallor or cyanosis in patients with dark skin tones. Usually you see colour hues best in the palms, soles of the feet, lips, tongue, and nail beds. Areas of increased colour (hyperpigmentation) and decreased colour (hypopigmentation) are common. Skin creases and folds are darker than the rest of the body in the dark-skinned patient.

Inspect sites where you are able to identify abnormalities more easily. For example, you can see pallor more easily in the face, buccal (mouth) mucosa, conjunctiva, and nail beds. Observe for cyanosis in the lips, nail beds, palpebral conjunctivae, and palms. In recognizing pallor in the dark-skinned patient, observe that normal brown skin appears to be yellow-brown and normal black skin appears to be ashen grey. Also assess the lips, nail beds, and mucous membranes for generalized pallor; if pallor is present, the mucous membranes will be ashen grey. Assessment of cyanosis in the dark-skinned patient requires observation of areas where pigmentation occurs the least (conjunctiva, sclera, buccal mucosa, tongue, lips, nail beds, and palms and soles). In addition, verify these findings with clinical manifestations (Marks & Miller, 2006).

The best site to inspect for **jaundice** (yellow-orange discoloration) is the patient's sclera. You can see normal reactive hyperemia, or redness, most often in regions exposed to pressure such as the sacrum, heels, and greater trochanter. Inspect for any patches or areas of skin colour variation. Localized skin changes, such as pallor or **erythema** (red discoloration),

Figure 31-5 A cross-section of the skin reveals three layers: epidermis, dermis, and subcutaneous fatty tissues.

TABLE 31-7 Nursing History for Skin Assessment

Assessment Category

Rationale

Ask patient about history of changes in the skin: dryness, pruritus, sores, rashes, lumps, colour, texture, odour, lesion that does not heal.

Patient is best source to recognize change. Usually skin cancer is first noticed as a localized change in skin colour.

Consider if the patient has the following history: fair, freckled, ruddy complexion; light-coloured hair or eyes; tendency to burn easily.

Characteristics are risk factors for skin cancer.

Determine whether patient works or spends excessive time outside. If so, ask whether patient wears sunscreen and the level of protection.

Exposed areas such as face and arms will be more pigmented than rest of body. The Canadian Cancer Society (2012b) recommends use of sunscreen.

Determine whether patient has noted lesions, rashes, or bruises.

Most skin changes do not develop suddenly. Change in character of lesion possibly indicates cancer. Bruising indicates trauma or bleeding disorder.

Question patient about frequency of bathing and type of soap used.

Excessive bathing and use of harsh soaps cause dry skin.

Ask if patient has had recent trauma to skin.

Some injuries cause bruising and changes in skin texture.

Determine whether patient has history of allergies.

Skin rashes commonly occur from allergies.

Ask if patient uses topical medications or home remedies on skin.

Incorrect use of topical agents causes inflammation or irritation.

Ask if patient goes to tanning parlours, uses sun lamps, or takes tanning pills.

Overexposure of skin to these irritants will possibly cause skin cancer.

Ask if patient has family history of serious skin disorders such as skin cancer or psoriasis.

Family history will possibly reveal information about patient's condition.

Determine if patient works with creosote, coal, tar, petroleum products, arsenic compounds, or radium.

Exposure to these agents creates risk for skin cancer.

► TABLE 31-8 Skin Colour Variations

Colour	Condition	Causes	Assessment Locations
Bluish (cyanosis)	Increased amount of deoxygenated hemoglobin (associated with hypoxia)	Heart or lung disease, cold environment	Nail beds, lips, mouth, skin (severe cases)
Pallor (decrease in colour)	Reduced amount of oxyhemoglobin	Anemia	Face, conjunctivae, nail beds, palms of hands
	Reduced visibility of oxyhemoglobin resulting from decreased blood flow	Shock	Skin, nail beds, conjunctivae, lips
Loss of pigmentation	Vitiligo	Congenital or autoimmune condition causing lack of pigment	Patchy areas on skin over face, hands, arms
Yellow-orange (jaundice)	Increased deposit of bilirubin in tissues	Liver disease, destruction of red blood cells	Sclera, mucous membranes, skin
Red (erythema)	Increased visibility of oxyhemoglobin caused by dilation or increased blood flow	Fever, direct trauma, blushing, alcohol intake	Face, area of trauma, sacrum, shoulders, other common sites for pressure ulcers
Tan-brown	Increased amount of melanin	Suntan, pregnancy	Areas exposed to sun: face, arms, areolae, nipples

► TABLE 31-9 Physical Findings of the Skin Indicative of Substance Abuse

Body System	Commonly Associated Drug
Diaphoresis	Sedative hypnotic (including alcohol)
Spider angiomas	Alcohol, stimulants
Burns (especially fingers)	Alcohol
Needle marks	Opioids
Contusion, abrasions, cuts, scars	Alcohol, other sedative hypnotics
"Homemade" tattoos	Cocaine, intravenous (IV) opioids (prevents detection of injection sites)
Increased vascularity of face	Alcohol
Red, dry skin	Phencyclidine (PCP)

Data from Reis, R. K., Fiellin, D. A., Miller, S. C., & Saitz, R. (Eds.) (2009). *Principles of addiction medicine: The essentials* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins; and Smith, D. E., & Seymour, R. B. (2001). *Clinician's guide to substance abuse*. New York: McGraw-Hill.

indicate circulatory changes. For example, an area of erythema is due to localized vasodilation resulting from a sunburn, inflammation, or fever. It is difficult to observe erythema in the dark-skinned patient, so palpate the area for heat and warmth to note the presence of skin inflammation (Jarvis et al., 2009). An area of an extremity that appears unusually pale results from arterial occlusion or edema. Be sure to ask if the patient has noticed any changes in skin colouring.

There is also a pattern of findings associated with patients who are chemically dependent or are intravenous (IV) drug abusers (Table 31-9). It is sometimes difficult to recognize signs and symptoms after one examination. A patient who takes repeated IV injections has edematous, reddened, and warm areas along the arms and legs. This pattern suggests recent injections. Evidence of old injection sites appears as hyperpigmented and shiny or scarred areas.

Moisture. The hydration of skin and mucous membranes helps to reveal body fluid imbalances, changes in the skin's environment, and regulation of body temperature. Moisture refers to wetness and oiliness. The skin is normally smooth and dry. Skin folds such as the axillae are normally moist. Minimal perspiration or oiliness is often present (Jarvis et al.,

2009). Increased perspiration is sometimes associated with activity, warm environments, obesity, anxiety, or excitement. Use ungloved fingertips to palpate skin surfaces and observe for dullness, dryness, crusting, and flaking. Flaking is the appearance of flakes resembling dandruff when the skin surface is lightly rubbed. Scaling involves fishlike scales that are easily rubbed off the skin's surface. Both flaking and scaling indicate abnormally dry skin. Excessively dry skin is common in older adults and individuals who use excessive amounts of soap during bathing. Other factors causing dry skin include lack of humidity, exposure to sun, smoking, stress, excessive perspiration, and dehydration. Excessive dryness worsens existing skin conditions such as **eczema** and **dermatitis**.

Temperature. The temperature of the skin depends on the amount of blood circulating through the dermis. Increased or decreased skin temperature indicates an increase or decrease in blood flow. An increase in skin temperature often accompanies localized erythema or redness of the skin. A reduction in skin temperature reflects a decrease in blood flow. It is important to remember that if an examination room is cold, this will affect the patient's skin temperature and colour.

Accurately assess temperature by palpating the skin with the dorsum, or back of the hand. Compare symmetrical body parts. Normally the skin temperature is warm. Sometimes skin temperature is the same throughout the body, and other times it varies in one area. Always assess skin temperature for patients at risk of having impaired circulation, such as after a cast application or vascular surgery. You can identify a stage I pressure ulcer early by noting warmth and erythema on an area of the skin (see Chapter 46).

Texture. The character of the skin's surface and the feel of deeper portions are its texture. Determine whether the patient's skin is smooth or rough, thin or thick, tight or supple, and **indurated** (hardened) or soft by stroking it lightly with the fingertips. The texture of the skin is normally smooth, soft, even, and flexible in children and adults. However, the texture is usually not uniform throughout. The palms of the hand and soles of the feet tend to be thicker. In older adults the skin becomes wrinkled and leathery because of a decrease in collagen, subcutaneous fat, and sweat glands.

Localized changes result from trauma, surgical wounds, or lesions. When finding irregularities in texture such as scars or induration, ask the patient if a recent injury to the skin has

Figure 31-6 Assessment for skin turgor. **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 164). St Louis, MO: Mosby.

occurred. Deeper palpation sometimes reveals irregularities such as tenderness or localized areas of induration commonly caused by repeated injections.

Turgor. Turgor is the skin's elasticity. Edema or dehydration diminish turgor. Normally the skin loses its elasticity with age. To assess the skin turgor, grasp a fold of skin on the back of the forearm or sternal area with the fingertips and release (Figure 31-6). Normally the skin lifts easily and snaps back immediately to its resting position. The back of the hand is not the best place to test for turgor, because the skin is normally loose and thin (Seidel et al., 2011). The skin stays pinched when turgor is poor. Note the ease with which the skin moves and the speed at which it returns to place. Failure of the skin to reassume its normal contour or shape indicates dehydration. The patient with poor skin turgor does not have a resilience to the normal wear and tear on the skin. The skin tends to stay pinched or tented when turgor is poor. A decrease in turgor predisposes the patient to skin breakdown.

Vascularity. The circulation of the skin affects colour in localized areas and the appearance of superficial blood vessels. With aging, capillaries become fragile. Localized pressure areas, found after a patient has remained in one position, appear reddened, pink, or pale (see Chapter 46). **Petechiae** are pinpoint-sized, red or purple spots on the skin caused by small hemorrhages in the skin layers. Petechiae do not blanch but may indicate serious blood-clotting disorders, drug reactions, or liver disease.

Edema. Areas of the skin become swollen or edematous from a buildup of fluid in the tissues. Direct trauma and impairment of venous return are two common causes of edema. Inspect edematous areas for location, colour, and shape. The formation of edema separates the skin's surface from the pigmented and vascular layers, masking skin colour. Edematous skin also appears stretched and shiny. Palpate edematous areas to determine mobility, consistency, and tenderness. When pressure from the examiner's fingers leaves an indentation in the edematous area, it is called pitting edema. To assess the degree of pitting edema, press the edematous area firmly with the thumb for several seconds and release. The depth of pitting, recorded in millimetres, determines the degree of edema (Seidel et al., 2011). For example, 1+ edema equals a 2-mm depth, 2+ edema equals a 4-mm depth, 3+ equals 6 mm, and 4+ equals 8 mm (see Figure 31-55, p. 589).

Lesions. The skin is normally free of lesions, except for common freckles or age-related changes such as skin tags, **senile keratosis** (thickening of skin), **cherry angiomas** (ruby-red papules), and atrophic warts. Lesions are primary (occurring as initial spontaneous manifestations of a pathological process), such as an insect bite, or secondary (resulting from later formation or trauma to a primary lesion), such as a pressure ulcer. When you detect a lesion, inspect it for colour, location, texture, size, shape, type, grouping (clustered or linear), and distribution (localized or generalized). Observe any exudate for colour, odour, amount, and consistency. Measure the size of the lesion by using a small, clear, flexible ruler divided in centimetres. Comparing a lesion with a household measure, such as a coin or eraser, is not reliable (Seidel et al., 2011). Measure lesions in height, width, and depth.

Palpation determines the lesion's mobility, contour (flat, raised, or depressed), and consistency (soft or indurated). Certain types of lesions present a characteristic pattern. For example, a tumour is usually an elevated, solid lesion larger than 2 cm. Primary lesions, such as macules and nodules, come from some stimulus to the skin (Box 31-7). Secondary lesions, such as ulcers, occur as alterations in primary lesions. After you identify a lesion, closely inspect it in good lighting. Palpate gently, covering the entire area of the lesion. If the lesion is moist or draining fluid, wear gloves during palpation.

Note if the patient complains of tenderness during palpation. Cancerous lesions frequently undergo changes in colour and size (Box 31-8). **Basal cell carcinoma** is most common in sun-exposed areas and frequently occurs in a background of sun-damaged skin; it almost never spreads to other parts of the body. **Squamous cell carcinoma** is more serious than basal cell and develops on the outer layers of sun-exposed skin; these cells may travel to lymph nodes and throughout the body. Report abnormal lesions to the health care provider for further examination.

Every nurse should be able to perform a complete examination of the skin and recognize abnormalities. Box 31-9 presents patient education that nurses should communicate while performing an examination of the integumentary system and in discussions about health screening.

safety alert Individuals exposed to the sun through sunbathing or artificial means increase their risk for development of skin cancer. Provide appropriate teaching to inform patients of ways to decrease their risk (see Boxes 31-6 and 31-8).

Hair and Scalp

The following types of hair cover the body: terminal hair (long, coarse, thick hair easily visible on the scalp, axillae, pubic areas, and in the beard in men) and vellus hair (small, soft, tiny hairs covering the whole body except for the palms and soles). Inspecting the condition and distribution of hair and the integrity of the scalp requires good lighting.

Inspection. During inspection, explain that it is necessary to separate parts of the hair to detect abnormalities. If lesions or lice are probable, wear clean gloves to avoid infection. Table 31-10 describes the nursing history for assessment of the hair and scalp.

First inspect the colour, distribution, quantity, thickness, texture, and lubrication of body hair. Scalp hair is coarse or fine; curly or straight; and should be shiny, smooth, and pliant. While separating sections of scalp hair, observe characteristics of colour and coarseness. Colour varies from very light blond

► BOX 31-7 Types of Primary Skin Lesions

Macule: Flat, nonpalpable change in skin colour, smaller than 1 cm (e.g., freckle, petech)

Papule: Palpable, circumscribed, solid elevation in skin, smaller than 1 cm (e.g., elevated nevus)

Nodule: Elevated solid mass, deeper and firmer than papule, 1–2 cm (e.g., wart)

Tumour: Solid mass that extends deep through subcutaneous tissue, larger than 1–2 cm (e.g., epithelioma)

Wheal: Irregularly shaped, elevated area or superficial localized edema; varies in size (e.g., hive, mosquito bite)

Vesicle: Circumscribed elevation of skin filled with serous fluid, smaller than 1 cm (e.g., herpes simplex, chicken pox)

Pustule: Circumscribed elevation of skin similar to vesicle but filled with pus; varies in size (e.g., acne, staphylococcal infection)

Ulcer: Deep loss of skin surface that extends to dermis and frequently bleeds and scars; varies in size (e.g., venous stasis ulcer)

Atrophy: Thinning of skin with loss of normal skin furrow, with skin appearing shiny and translucent; varies in size (e.g., arterial insufficiency)

to black to grey and sometimes shows alterations from rinses or dyes. In older adults, the hair becomes dull grey, white, or yellow. The hair also thins over the scalp, axillae, and pubic areas. Older men often lose facial hair, whereas some older women develop hair on the chin and upper lip.

Be aware of the normal distribution of hair growth in a man and a woman. At puberty, a change in the amount and distribution of hair growth occurs. Some patients with hormone disorders experience an unusual distribution and growth. A woman with **hirsutism** has hair growth on the upper lip, chin, and cheeks, with vellus hair becoming coarser over the body. For some, a change in hair growth negatively affects body image and emotional well-being.

Some changes occur in the thickness, texture, and lubrication of scalp hair. Disturbances such as a febrile illness or scalp disease sometimes result in hair loss. Conditions such as thyroid disease alter the condition of the hair, making it fine and brittle. Hair loss (**alopecia**) or thinning of the hair is usually related to genetic tendencies and endocrine disorders such as diabetes, thyroiditis, and even menopause. Poor nutrition

causes stringy, dull, dry, and thin hair. The oil of sebaceous glands lubricates the hair. Excessively oily hair is associated with androgen hormone stimulation. Dry, brittle hair occurs with aging and with excessive use of chemical agents.

The amount of hair covering the extremities is sometimes reduced as a result of aging. Arterial insufficiency is most common over the lower extremities. In women, do not confuse a loss of hair with shaven legs.

Inspect the scalp for lesions, which are not easy to notice in thick hair. The scalp is normally smooth and inelastic, with even colouration. By carefully separating strands of hair, thoroughly examine the scalp for lesions. Note the characteristics of any scalp lesion. If you find lumps or bruises, ask if the patient has experienced recent head trauma. Moles on the scalp are common. Warn the patient that combing or brushing sometimes causes a mole to bleed. Dandruff or psoriasis frequently causes scaliness or dryness of the scalp.

Careful inspection of hair follicles on the scalp and pubic areas will possibly reveal lice or other parasites. The three types of lice are *Pediculus humanus capitis* (head lice), *Pediculus*

► BOX 31-8 Skin Malignancies

Basal Cell Carcinoma

0.5 to 1.0 cm crusted lesion that is flat or raised and has a rolled, somewhat scaly border.

Frequently there are underlying, widely dilated blood vessels that appear within the lesion.

Basal Cell Carcinoma

Squamous Cell Carcinoma

Occurs more often on mucosal surfaces and nonexposed areas of skin, compared with basal cell.

0.5 to 1.5 cm scaly lesion is sometimes ulcerated or crusted.

Appears frequently and grows more rapidly than basal cell.

Basal Squamous Cell Carcinoma

Melanoma

0.5 to 1.0 cm brown, flat lesion that appears on sun-exposed or nonexposed skin. Variegated pigmentation, irregular borders, and indistinct margins.

Ulceration, recent growth, or recent changes in long-standing mole are ominous signs.

Melanoma

Illustrations from Marks, J., & Miller, J. (Eds.) (2006). *Lookingbill and Mark's principles of dermatology* (4th ed.). Philadelphia, PA: Elsevier; **Basal cell**: p. 65, Fig 5-14A; **Squamous cell**: p. 63, Fig 5-12. **Melanoma**: From Paller, A. S., & Mancini, A. J. (2011). *Hurwitz clinical pediatric dermatology* (4th ed., p. 192, Fig 9.18). Edinburgh: Elsevier/Saunders.

humanus corporis (body lice), and *Pediculus pubis* (crab lice). Head and crab lice attach their eggs to hair. The tiny eggs look like oval particles of dandruff. The lice themselves are difficult to see. Head and body lice are very small with greyish white bodies. Crab lice have red legs. Observe for bites or pustular eruptions in the hair follicles and in areas where skin surfaces meet, such as behind the ears and in the groin. The discovery of lice requires immediate treatment (Box 31-10).

Nails

The condition of the nails reflects general health, state of nutrition, a person's occupation, and level of self-care. Nail biting can reveal a person's psychological state. Before assessing the

nails, gather a brief history (Table 31-11). The most visible portion of the nails is the nail plate, the transparent layer of epithelial cells covering the nail bed (Figure 31-7). The vascularity of the nail bed creates the nail's underlying colour. The semilunar, whitish area at the base of the nail bed is called the lunula, from which the nail plate develops.

Inspection and Palpation. Inspect the nail bed for colour, cleanliness, and length; the thickness and shape of the nail, the texture of the nail; the angle between the nail and the nail bed; and the condition of the lateral and proximal nail folds around the nail. Also palpate the nail base. When inspecting the nails, you will obtain a quick sense about the patient's hygiene practices. The nails are normally transparent, smooth,

✱ BOX 31-9 EVIDENCE-INFORMED PRACTICE GUIDELINE

Skin Cancer Prevention

Research Summary

What is cancer? More specifically, what is skin cancer? Cancer by definition is an “uncontrolled growth and spread of abnormal cells” (CCS Steering Committee, 2010). Therefore, skin cancer is characterized by abnormal skin cells, which can spread and invade other tissues. More importantly, what can we do about skin cancer? As nurses, it becomes our responsibility to assess for and educate our patients about all types of skin cancers, especially for the most serious form called melanoma. There are several risk factors for melanoma: major factors are positive family history of melanoma, a prior melanoma, and multiple or unusual moles. Other factors include fair complexion or skin that is sensitive to the sun; excessive exposure to the sun (especially before age 18), and the use of tanning beds or booths.

Research has indicated that skin cancer, when detected early and treated properly, is highly curable (CCS Steering Committee, 2010). Therefore early assessment and intervention is of utmost importance.

Application to Nursing Practice

Nurses have a responsibility to screen and intervene if it is in their patients’ best interest. Promoting and teaching self-screening of skin, hair, and nails for all patients and their family members is one area where nurses have a large role.

- Instruct patients to conduct a complete monthly self-examination of the skin and scalp, noting moles, blemishes, and birthmarks.
- Perform the examination after a bath or shower, including a head-to-toe check.
- Use a well-lit room and mirrors to examine all skin surfaces. If necessary, have the patient ask a family member or significant other to aid in the investigation.

- Remember the warning signs of skin cancer using the ABCD mnemonic: A is for Asymmetry—look for uneven shape; B is for Border irregularity—look for edges that are blurred, notched, or ragged; C is for Colour—pigmentation is not uniform; blue, black, brown variegated and areas of pink, white, grey, blue, or red are abnormal; and D is for Diameter, greater than the size of a typical pencil eraser.
- Teach your patients to contact their health care provider if a skin lesion or mole starts to bleed or ooze or feels different (swollen, hard, lumpy, itchy, or tender to the touch). Especially instruct older adults, who tend to have delayed wound healing.
- Inform your patients of ways to prevent skin cancer by avoiding overexposure to the sun:
 - Wear wide-brimmed hats and long sleeves.
 - Apply broad-spectrum sunscreens with SPF of 15 or greater to protect against ultraviolet B (UVB) and ultraviolet A (UVA) rays approximately 15 minutes before going into the sun and after swimming or perspiring.
 - Avoid tanning under the direct sun at midday (10 A.M. to 4 P.M.).
 - Do not use indoor sunlamps, tanning parlours, or tanning pills.
- Inform patients who are on medications that make the skin more sensitive to the sun (e.g., oral contraceptives, antibiotics, anti-inflammatories, antihypertensives, immunosuppressives) to take extra precautions when spending time in the sun.
- Inform patients to protect their children from the sun. Severe sunburns in childhood greatly increase melanoma risk later in life (Canadian Cancer Society, 2012b).

These interventions will provide the patient with self-screening measures to detect, prevent, and seek early treatment for skin cancer.

Data from Canadian Cancer Society. (2012). *Prevention*. Retrieved from http://www.cancer.ca/Canada-wide/Prevention.aspx?sc_lang=EN.

TABLE 31-10

Nursing History for Hair and Scalp Assessment

Assessment Category

Rationale

Ask patient if he or she is wearing a wig or hairpiece, and ask him or her to remove it.	Wigs or hairpieces interfere with inspection of hair and scalp. (Patient sometimes requests to omit this part of examination.)
Determine if patient has noted change in growth or loss of hair; change in texture or colour.	Change often occurs slowly over time.
Identify type of hair care products used for grooming.	Excessive use of chemical agents and burning of hair causes drying and brittleness.
Determine if patient has recently had chemotherapy (drugs that cause hair loss) or taken a vasodilator (minoxidil) for hair growth.	Chemotherapeutic agents kill cells that rapidly multiply, such as tumour cells and normal hair cells. Minoxidil causes excessive hair growth.
Has patient noted changes in diet or appetite?	Nutrition influences condition of hair.

well rounded, and convex, with a nail bed angle of about 160 degrees. The surrounding cuticles are smooth, intact, and without inflammation. If the nails are ragged, dirty, and poorly kept, this is a good indication that either the patient practises infrequent nail care or is physically unable to perform care. However, consider the patient’s profession, because some individuals have dirty nails as part of their employment (e.g., mechanics, coal miners, and farmers) despite excellent nail care. Jagged, bitten, or broken nail edges or cuticles predispose a patient to localized infection. Report any abnormalities such as erythema or swelling.

safety alert Patients with impaired circulation are at greater risk for localized infection. It is important to observe the condition of hand and foot nails and nail beds to identify risks for and early signs of infection.

In light-skinned individuals, nail beds are pink with translucent white tips. In dark-skinned patients, nail beds are darkly pigmented with a blue or reddish hue. A brown or black pigmentation is normal with longitudinal streaks (Figure 31-8). Trauma, **cirrhosis**, diabetes mellitus, and hypertension cause splinter hemorrhages. Vitamin, protein, and electrolyte changes cause various lines or bands to form on the nail beds.

Nails normally grow at a constant rate, but direct injury or generalized disease impairs growth. With aging, the nails of the fingers and toes become harder and thicker. Longitudinal

BOX 31-10 PATIENT TEACHING

Hair and Scalp Assessment

Objective

- Patient will perform proper hygiene practices for care of the hair and scalp.

Teaching Strategies

- Instruct patient about basic hygiene practices for care of the hair and scalp (see Chapter 37).
- Instruct patients who have head lice to shampoo thoroughly with pediculicide shampoo (available at drugstores) in cold water, comb thoroughly with a fine-tooth comb (following product directions), and discard comb. Caution against use of products containing lindane, a toxic ingredient known to cause adverse reactions. Repeat shampoo treatment following product directions.
- After combing, remove any detectable nits or nit cases with tweezers or between the fingernails. A dilute solution of vinegar and water helps loosen nits.
- Instruct patients and parents about ways to reduce transmission of lice:
 - Do not share personal care items with others.
 - Vacuum all rugs, car seats, pillows, furniture, and flooring thoroughly, and discard vacuum bag.
 - Seal nonwashable items in plastic bags for 14 days if unable to dry-clean or vacuum.
 - Use thorough hand hygiene practices.
 - Launder all clothing, linen, and bedding in hot soap and water, and dry in a hot dryer for at least 20 minutes. Dry-clean nonwashable items.
 - Do not use insecticide.
 - Instruct patient to notify his or her partner if lice were sexually transmitted.
 - Avoid physical contact with infested individuals and their belongings, especially clothing and bedding.
 - Soak combs, brushes, and hair accessories in lice-killing products for one hour or in boiling water for 10 minutes.

Evaluation

- Have patient describe methods used to care for the hair and scalp.
- Have patient explain the steps to take to reduce lice transmission in the home.

Data from Tebruegge, M., Pantazidou, A., & Curtis, N. (2010). What's bugging you? An update on the treatment of head lice infestation. *Archives of Diseases in Childhood*, 96, 2–8 doi:10.1136/adc.2009.178038; and Canadian Pediatric Society. (2010). *Head lice*. Retrieved from <http://www.caringforkids.cps.ca/whensick/HeadLice.htm>.

striations develop, and the rate of nail growth slows. Nails become more brittle, dull, and opaque and turn yellow in older adults because of insufficient calcium. Also with age, the cuticle becomes less thick and wide.

Inspection of the angle between the nail and nail bed normally reveals an angle of 160 degrees (Box 31-11). A larger angle and softening of the nail bed indicates chronic oxygenation problems. Palpate the nail base to determine firmness and the condition of circulation. The nail base is normally firm.

To palpate, gently grasp the patient's finger and observe the colour of the nail bed. Next, apply gentle, firm, quick pressure with the thumb to the nail bed and release and observe **capillary refill**. As you apply pressure, the nail bed will appear white or blanched; however, the pink colour should return

► TABLE 31-11

Nursing History for Nail Assessment

Assessment Category

Ask if patient has experienced recent trauma or changes in nails (splitting, breaking, discolouration, thickening).

Has the patient had other symptoms of pain, swelling, presence of systemic disease with fever, or psychological or physical stress?

Question patient's nail care practices. Determine if patient has acrylic nails or silk wraps.

Determine if patient has risks for nail or foot problems (e.g., diabetes, peripheral vascular disease, older adulthood, obesity).

Rationale

Trauma changes shape and growth of nail. Systemic conditions cause changes in colour, growth, and shape.

Alterations sometimes occur slowly over time.

Helps to indicate if change in nails is due to local or systemic problem. Acrylic nails and silk wraps are areas for fungal growth.

Chemical agents cause drying of nails. Improper care damages nails and cuticles.

Vascular changes associated with diabetes and peripheral vascular disease reduce blood flow to peripheral tissues; foot lesions and thickened nails are common. Some older adults have trouble performing foot and nail care because of poor vision, incoordination, or inability to bend over. Obese patients have difficulty bending over.

immediately on release of pressure. Capillary refill is measured in seconds; less than two seconds is brisk, while greater than four seconds is sluggish. Failure of the pinkness to return promptly indicates circulatory insufficiency. An ongoing bluish or purplish cast to the nail bed occurs with cyanosis. A white cast or pallor results from anemia.

Calluses and corns are commonly found on the toes or fingers. A callus is flat and painless, resulting from a thickening of the epidermis. Friction and pressure from shoes cause corns, usually over bony prominences. During the examination, instruct the patient in proper nail care (Box 31-12).

Head and Neck

An examination of the head and neck includes assessment of the head, eyes, ears, nose, mouth, pharynx, and neck (lymph nodes, carotid arteries, thyroid gland, and trachea). This assessment is commonly referred to in clinical documentation under EENT (eyes, ears, nose, and throat) and includes all of the associated physical structures (e.g., peripheral arteries and carotid arteries). Assessment of the head and neck uses inspection, palpation, and auscultation, with inspection and palpation often used simultaneously.

Head

Inspection and Palpation. The nursing history screens for intracranial injury and local or congenital deformities

Figure 31-7 Components of the nail unit. Redrawn from Thompson, J. M., et al. (2001). *Mosby's clinical nursing* (5th ed.). St Louis, MO: Mosby.

Figure 31-8 Pigmented bands in nail of patient with dark skin.
Source: From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 175). St Louis, MO: Mosby.

(Table 31-12). Inspect the patient's head, noting the position, size, shape, and contour. The head is normally held upright and midline to the trunk. Holding the head tilted to one side is perhaps an indication of unilateral hearing or visual loss. A horizontal jerking or bobbing indicates a tremor.

Note the patient's facial features, looking at the eyelids, eyebrows, nasolabial folds, and mouth for shape and symmetry. It is normal for slight asymmetry to exist. If there is facial asymmetry, note if all features on one side of the face are affected or if only a portion of the face is involved. Various neurological disorders (e.g., facial nerve paralysis) affect different nerves that innervate muscles of the face.

Examine the size, shape, and contour of the skull. The skull is generally round with prominences in the frontal area anteriorly and the occipital area posteriorly. Trauma typically causes local skull deformities. In infants, a large head results from congenital anomaly or the buildup of cerebrospinal fluid in the ventricles (**hydrocephalus**). Some adults have enlarged jaws and facial bones resulting from **acromegaly**, a disorder caused by excessive secretion of growth hormone. Palpate the

► BOX 31-11 Abnormalities of the Nail Bed

Normal nail: Approximately 160-degree angle between nail plate and nail

Clubbing: Change in angle between nail and nail base (eventually larger than 180 degrees); nail bed softening, with nail flattening; often, enlargement of fingertips
Causes: Chronic lack of oxygen: heart or pulmonary disease

Beau's lines: Transverse depressions in nails indicating temporary disturbance of nail growth (nail grows out over several months)

Causes: Systemic illness such as severe infection; nail injury

Koilonychia (spoon nail):

Concave curves

Causes: Iron deficiency anemia, syphilis, use of strong detergents

Splinter hemorrhages: Red or brown linear streaks in nail bed
Causes: Minor trauma, subacute bacterial endocarditis, trichinosis

Paronychia: Inflammation of skin at base of nail

Causes: Local infection, trauma

BOX 31-12 PATIENT TEACHING

Nail Assessment

Objective

- Patient properly cares for fingernails, feet, and toenails.

Teaching Strategies

- Instruct patient to cut nails only after soaking them about 10 minutes in warm water. (Exception: Diabetic patients are warned against soaking nails because this dries the hands and feet out; dry skin leads to infection.)
- Caution patient against over-the-counter preparations to treat corns, calluses, or ingrown toenails.
- Tell the patient to cut nails straight across and even with the tops of the fingers or toes. If patient has diabetes, tell patient to file rather than cut the nails (see Chapter 37).
- Instruct patient to shape nails with a file or emery board.
- If patient is diabetic:
 - Wash feet daily in warm water, and carefully dry them, especially between the toes. Inspect feet each day in good lighting, looking for dry places and cracks in the skin. Soften dry feet by applying a cream or lotion such as Nivea, Eucerin, or Alpha Keri.
 - Do not put lotion between the toes; moisture between the toes allows microorganisms to grow, leading to infections.
 - Caution patient against using sharp objects to poke or dig under the toenail or around the cuticle.
 - Have patient see a podiatrist for treatment of ingrown toenails and nails that are thick or tend to split.

Evaluation

- Inspect nails during subsequent patient interactions.
- Have patient explain steps to take to avoid injury.

Figure 31-9 Cross-section of the eye.

skull for nodules or masses. Gently rotate the fingertips down the midline of the scalp and then along the sides of the head to identify abnormalities. Then palpate the temporomandibular joint (TMJ) space bilaterally. Place the fingertips just anterior to the tragus of each ear. The fingertips should slip into the joint space as the patient's mouth opens, to gently palpate the joint spaces. Normally, the movements should be smooth, although it is not unusual to hear or feel a clicking or snapping in the TMJ (Seidel et al., 2011).

Eyes

Examination of the eyes includes inspection of external and internal eye structures and extraocular movement and the assessment of visual acuity and visual fields. Figure 31-9 shows a cross-section of the eye. The assessment detects visual alterations and determines the level of assistance that patients require when ambulating or performing self-care activities. Some patients with visual problems also need special aids for reading educational materials or instructions (e.g., medication labels). Table 31-13 reviews the nursing history for an eye examination. Box 31-13 describes common types of visual problems.

External Eye Structures

To inspect external eye structures, stand directly in front of the patient at eye level and ask the patient to look at your face.

Position and Alignment

Assess the position of the eyes in relation to one another. Normally, they are parallel to each other. Bulging eyes (**exophthalmos**) usually indicate hyperthyroidism. The crossing of eyes (**strabismus**) results from neuromuscular injury or inherited abnormalities. Tumours or inflammation of the orbit often cause abnormal eye protrusion.

For the remainder of the eye examination, have the patient remove contact lenses.

Eyebrows. Inspect the eyebrows for size, extension, texture of hair, alignment, and movement. Normally, the eyebrows are symmetrical. Coarseness of hair and failure to extend beyond the temporal canthus possibly reveals hypothyroidism. If the brows are thinned, this is possibly a result of waxing or plucking. Aging causes loss of the lateral third of the eyebrows. Have the patient raise and lower the eyebrows. The brows normally raise and lower symmetrically. An

TABLE 31-12 Nursing History for Head Assessment

Assessment Category	Rationale
Determine if patient experienced recent head trauma. If so, assess state of consciousness after injury (immediately on return and 5 minutes later), duration of unconsciousness, and predisposing factors (e.g., seizure, poor vision, blackout).	Trauma is major cause for lumps, bumps, cuts, bruises, or deformities of scalp or skull. Loss of consciousness following head injury indicates possible brain injury.
Ask if patient has history of headache; note onset, duration, character, pattern, and associated symptoms.	Character of headache helps to reveal causative factors such as sinus infection, migraine, or neurological disorders.
Determine length of time patient has experienced neurological symptoms.	Duration of signs or symptoms reveals severity of problem.
Review patient's occupational history for use of safety helmets.	Nature of some occupations creates a risk for head injury.
Ask if patient participates in contact sports, cycling, inline skating, or skateboarding.	These activities require use of safety helmets.

▶ TABLE 31-13

Nursing History for Eye Assessment

Assessment Category

Rationale

Determine if patient has history of eye disease, (e.g., glaucoma, retinopathy, cataracts), eye trauma, diabetes, hypertension, or eye surgery.

Some diseases or trauma cause risk for partial or complete visual loss. Patient may have had surgery for a visual disorder.

Determine problems that prompted patient to seek health care. Ask patient about eye pain, photophobia (sensitivity to light), burning or itching, excess tearing or crusting, diplopia (double vision) or blurred vision, awareness of a "film" or "curtain" over field of vision, floaters (small, black spots that seem to float across field of vision), flashing lights, or halos around lights.

Common symptoms of eye disease indicate need for health care provider.

Determine whether there is family history of eye disorders or diseases.

Certain eye problems such as glaucoma or retinitis pigmentosa are inherited.

Review patient's occupational history and recreational hobbies; are safety glasses worn?

Performance of close, intricate work causes eye fatigue. Working with computers causes eye strain. Certain occupational tasks (e.g., working with chemicals) and recreational activities (e.g., fencing, motorcycle riding) place people at risk for eye injury unless patients take precautions.

Ask patient if he or she wears glasses or contacts and if so, how often.

Patients need to wear glasses or contacts during certain portions of examination for accurate assessment.

Determine when patient last visited ophthalmologist or optometrist.

Date of last eye examination reveals level of preventive care patient takes.

Assess medications patient is taking, including eye drops or ointment.

Determines need to assess patient's knowledge of medications. Certain medications cause visual symptoms.

▶ BOX 31-13

Common Eye and Visual Problems

Hyperopia

Hyperopia is farsightedness, a refractive error in which rays of light enter the eye and focus behind the retina. Individuals are able to clearly see distant objects but not close objects.

Myopia

Myopia is nearsightedness, a refractive error in which rays of light enter the eye and focus in front of the retina. Individuals are able to clearly see close objects but not distant objects.

Presbyopia

Presbyopia is impaired near vision in middle-aged and older adults, caused by loss of elasticity of the lens and associated with the aging process.

Retinopathy

Retinopathy is a noninflammatory eye disorder resulting from changes in retinal blood vessels. It is a leading cause of blindness.

Strabismus

Strabismus is a (congenital) condition in which both eyes do not focus on an object simultaneously; these eyes appear crossed. Impairment of the extraocular muscles or their nerve supply causes strabismus.

Amblyopia

Amblyopia is a (congenital) condition, commonly referred to as a "lazy eye," and occurs when the nerve pathway in one eye does not develop in early childhood. This weakness to one eye can result in blurred vision, distortion of depth perception, or progressive vision loss to the affected eye. Early screening and referral of children for amblyopia and strabismus is important to correct and preserve vision.

Cataracts

A cataract is an increased opacity of the lens, which blocks light rays from entering the eye. Cataracts sometimes develop slowly and progressively after age 35 or suddenly after trauma. Cataracts are one of the most common eye disorders. Most older adults (65 year old and up) have some evidence of visual impairment from cataracts. Protection of the eyes from the sun's rays and trauma through the use of sunglasses and protective eye wear when there is an occupational or recreational risk for eye injury is an important factor in the prevention of cataracts.

Glaucoma

Glaucoma is intraocular structural damage resulting from elevated intraocular pressure. Obstruction of the outflow of aqueous humor causes this. Without treatment, the disorder will lead to blindness.

Macular Degeneration

Macular degeneration is blurred central vision often occurring suddenly, caused by a progressive degeneration of the centre of the retina. It is the most common visual impairment of individuals over age 50 and the most common cause of blindness in older adults. There is no cure.

inability to move the eyebrows indicates a facial nerve paralysis (cranial nerve VII).

Eyelids. Inspect the eyelids for position, colour, condition of the surface, condition and direction of the eyelashes, and the patient's ability to open, close, and blink. When the eyes are open in a normal position, the lids do not cover the pupil and you cannot see the sclera above the iris. The lids are also close to the eyeball. An abnormal drooping of the lid over the pupil is called **ptosis** (pronounced "toe-sis"), caused by edema or impairment of the third cranial nerve. In the older adult,

ptosis results from a loss of elasticity that accompanies aging. Observe for defects in the position of the lid margins. An older adult frequently has lid margins that turn out (**ectropion**) or in (**entropion**). An entropion sometimes leads to the lashes of the lid irritating the conjunctiva and cornea, increasing the risk of infection. The eyelashes are normally distributed evenly and curved outward away from the eye. An erythematous or yellow lump (hordeolum or sty) on the follicle of an eyelash indicates an acute suppurative inflammation.

Figure 31-10 The lacrimal apparatus secretes and drains tears, which moisten and lubricate eye structures.

To inspect the surface of the upper lids, ask the patient to close his or her eyes. Then raise both eyebrows gently with the thumb and index finger to stretch the skin. The lids are normally smooth and the same colour as the skin. Redness indicates inflammation or infection. Lid edema is sometimes due to allergies or to heart or kidney failure. Edema of the eyelids prevents them from closing. Inspect lesions for typical characteristics and discomfort or drainage. Wear clean gloves if drainage is present.

The lids normally close symmetrically. Failure of the lids to close exposes the cornea to drying. This condition is common in unconscious patients or in those with facial nerve paralysis. Ask the patient to open the eyes for inspection of the lower lids. You assess the same characteristics noted for the upper lids. Normally a patient blinks involuntarily and bilaterally up to 20 times a minute. The blink reflex lubricates the cornea. Report absent or infrequent, rapid, or monocular (one-eyed) blinking.

Lacrimal Apparatus. The lacrimal gland (Figure 31-10), located in the upper outer wall of the anterior part of the orbit, is responsible for tear production. Tears flow from the gland across the eye's surface to the lacrimal duct, which is in the nasal corner or inner canthus of the eye. The lacrimal gland is sometimes the site of tumours or infections. Inspect this area for edema and redness. Palpate the gland gently to detect tenderness. Normally you cannot feel the gland.

The nasolacrimal duct sometimes becomes obstructed, blocking the flow of tears. Observe for evidence of edema in the inner canthus. Gentle palpation of the duct at the lower eyelid just inside the lower orbital rim causes a regurgitation of tears.

Conjunctivae and Sclerae. The bulbar conjunctiva covers the exposed surface of the eyeball up to the outer edge of the cornea. Observe the sclera under the bulbar conjunctiva; it normally has the colour of white porcelain in whites and light yellow in dark-skinned patients. Sclerae become pigmented and appear either yellow or green if liver disease is present.

Take care when inspecting the conjunctivae. For adequate exposure of the bulbar conjunctiva, retract the eyelids without placing pressure directly on the eyeball. Gently retract both lids, with the thumb and index finger pressed against the lower and upper bony orbits. Ask the patient to look up, down, and from side to side. Many patients begin to blink, making

Figure 31-11 Chart depicting pupillary size in millimetres.

the examination difficult. Inspect for colour, texture, and the presence of edema or lesions. Normally the conjunctivae are free of erythema. The presence of redness indicates an allergic or infectious **conjunctivitis**. Bright red blood in a localized area surrounded by normal-appearing conjunctiva usually indicates subconjunctival hemorrhage. Conjunctivitis is a highly contagious infection. It is easy to spread the crusty drainage that collects on eyelid margins from one eye to the other. Wear clean gloves during the examination. Performing proper hand hygiene is necessary before and after the examination.

Corneas. The cornea is the transparent, colourless portion of the eye covering the pupil and iris. From a side view, it looks like the crystal of a wristwatch. While the patient looks straight ahead, inspect the cornea for clarity and texture while shining a penlight obliquely across the cornea's entire surface. The cornea is normally shiny, transparent, and smooth. In older adults, the cornea loses its lustre. Any irregularity in the surface indicates an abrasion or tear that requires further examination by a health care provider. Both conditions are very painful. Note the colour and details of the underlying iris. In an older adult, the iris becomes faded. A thin white ring along the margin of the iris, called an **arcus senilis**, is common with aging but is abnormal in anyone under age 40. To test for the corneal blink reflex, see the cranial nerve test section of this chapter.

Pupils and Irises. Observe the pupils for size, shape, equality, accommodation, and reaction to light. The pupils are normally black, round, regular, and equal in size (3 to 7 mm in diameter) (Figure 31-11). The iris should be clearly visible.

Cloudy pupils indicate cataracts. Dilated pupils result from glaucoma, trauma, neurological disorders, eye medications (e.g., atropine), or withdrawal from opioids. Inflammation of the iris or use of drugs (e.g., pilocarpine, morphine, or cocaine) causes constricted pupils. Pinpoint pupils are a common sign of opioid intoxication. Shining a beam of light through the pupil and onto the retina stimulates the third cranial nerve and causes the muscles of the iris to constrict. Any abnormality along the nerve pathways from the retina to the iris alters the ability of the pupils to react to light. Changes in intracranial pressure, lesions along the nerve pathways, locally applied ophthalmic medications, and direct trauma to the eye alter pupillary reaction.

Test pupillary reflexes (to light and accommodation) in a dimly lit room. While the patient looks straight ahead, bring a penlight from the side of the patient's face, directing the light onto the pupil (Figure 31-12). If the patient looks at the light, there will be a false reaction to accommodation. A directly illuminated pupil constricts, and the opposite pupil constricts consensually. Observe the quickness and equality of the reflex. Repeat the examination for the opposite eye.

To test for accommodation, ask the patient to gaze at a distant object (the far wall) and then at a test object (finger or pencil) held approximately 10 cm from the bridge of the patient's nose. The pupils normally converge and accommodate by constricting when looking at close objects. The pupillary responses are equal. Testing for accommodation is

Figure 31-12 A, To check pupillary reflexes, the nurse first holds the penlight to the side of the patient's face. B, Illumination of the pupil causes pupillary constriction.

important only if the patient has a defect in the pupillary response to light (Jarvis et al., 2009). If assessment of pupillary reaction is normal in all tests, record the abbreviation **PERRLA** (pupils equal, round, reactive to light, and accommodation).

Internal Eye Structures. The examination of the internal eye structures through the use of an ophthalmoscope is beyond the scope of new graduate nurses' practice. Advanced nurse practitioners use the **ophthalmoscope** to inspect the fundus (Figure 31-13), which includes the retina, choroid, optic nerve disc, macula, fovea centralis, and retinal vessels. Patients in greatest need of an examination are those with diabetes, hypertension, and intracranial disorders.

Extraocular Movements. Six small muscles guide the movement of each eye. Both eyes move parallel to each other in each of the six directions of gaze (Figure 31-14). To assess extraocular movements, have the patient sit or stand 60 cm away, facing you. Hold a finger at a comfortable distance (15 to 30 cm) from the patient's eyes. Have the patient maintain his or her head in a fixed position facing forward and follow the movement of the finger with the eyes only. Have the patient look to the right, to the left, and diagonally up and down to the left and right. The finger moves smoothly and slowly within the normal field of vision.

Figure 31-13 Fundus of, A, white patient. B, Black patient. Courtesy MEDCOM, Cypress, CA.

Figure 31-14 Six directions of gaze. Direct the patient to follow finger movement through each gaze. **Source:** From Seidel H. M., et al. (2011). *Mosby's guide to physical examination*, (7th ed., p. 278). St Louis, MO: Mosby.

As the patient gazes in each direction, observe for parallel eye movement, the position of the upper eyelid in relation to the iris, and the presence of abnormal movements. As the eyes move through each direction of gaze, the upper eyelid covers the iris only slightly. You assess **nystagmus**, an involuntary, rhythmical oscillation of the eyes, by periodically stopping movement of the finger. You initiate nystagmus in patients with normal eye movements by having them gaze to the far left or right. Disturbances in eye movement reflect local injury to eye muscles and supporting structures or a disorder of the cranial nerves innervating the muscles.

Visual Fields. As a person looks straight ahead, he or she is normally able to see all objects in the periphery. To assess visual fields, have the patient stand or sit 60 cm away, facing you at eye level. The patient gently closes or covers one eye (e.g., the left) and looks at your eye directly opposite. Close the opposite eye (in this case the right) so that the field of vision is superimposed on that of the patient. Move a finger equidistant from you and the patient outside the field of vision, then slowly bring it back into the visual field. Ask the patient to tell when he or she is able to see the finger. If you see the finger before the patient does, a portion of the patient's visual field is reduced. To test temporal field vision, the object should be slightly behind the patient. (Note: The nurse can see the finger.) Repeat the procedure for each field of vision for the other eye.

safety alert Some patients with visual field problems are at risk for injury because they cannot see all the objects in front of them. Older adults commonly have loss of peripheral vision caused by changes in the lens.

Visual Acuity. The assessment of visual acuity, the ability to see small details, tests central vision. The easiest way to assess near vision is to ask patients to read printed material under adequate lighting. If patients wear glasses, make sure they wear them during assessment. Determine the language the patient speaks and reading ability. Asking patients to read aloud will help determine literacy. If the patient has difficulty reading, move to the next step.

Assessment of distant vision requires using a Snellen chart (paper chart or projection screen). The chart is well lighted. Test vision without corrective lenses first. Have the patient sit or stand 6.1 m (20 feet) away from the chart and try to read all the letters beginning at any line with both eyes open. Then have the patient read the line with each eye separately (patient covers the opposite eye with an index card or eye cover). The patient avoids applying pressure to the eye. Note the smallest line in which the patient is able to read all the letters correctly, and record the visual acuity for that line. Repeat the test with the patient wearing corrective lenses. Complete the test rapidly enough so that the patient does not memorize the chart (Jarvis et al., 2009).

If a patient is unable to read, use an *E* chart or one with pictures of familiar objects. Instead of reading letters, patients tell which direction each *E* is pointing or the name of the object. Record the visual acuity score for each eye and for both eyes.

The Snellen chart has standardized numbers at the end of each line of the chart. The numerator is the number 20, or the distance the patient stands from the chart. The denominator is the distance from which the normal eye is able to read the chart. Normal vision is 20/20. The larger the denominator, the poorer the patient's visual acuity. For example, a value of 20/40 means that the patient, standing 6.1 m (20 feet) away, can read a line that a person with normal vision can read from 40 feet away. Record visual acuity as O.D. (right eye) and O.S. (left eye) as well as *sc* (without correction) or *cc* (with correction), depending on whether the patient wears glasses or contact lenses.

If patients cannot read even the largest letters or figures of a Snellen chart, test their ability to count upraised fingers or distinguish light. Hold a hand 30 cm from the patient's face, and have the patient count the upraised fingers. To check light perception, shine a penlight into the eye and then turn the light off. If the patient notes when the light is turned on or off, light perception is intact.

You assess near vision by asking the patient to read a hand-held card containing a vision screening chart. Instruct the patient to hold the card a comfortable distance (5 to 6 cm) from the eyes and read the smallest line possible. This portion of the examination is a good time to discuss the need for routine eye examinations (see Box 31-14).

Ears

The ear assessment determines the integrity of ear structures and hearing acuity (Box 31-15). The three parts of the ear are the external, middle, and inner ear (Figure 31-15). Inspect and palpate external ear structures, inspect middle ear structures with an otoscope, and test the inner ear by measuring the

BOX 31-14 PATIENT TEACHING

Eye Assessment

Objectives

- Patient follows recommendations for regular eye examinations.
- Patient recognizes warning signs and symptoms of eye disease.
- Patient takes appropriate safety precautions for visual deficits.

Teaching Strategies

- Tell patient that people under age 40 need to have a complete eye examination every three to five years (or more often if family histories reveal risks such as diabetes or hypertension).
- Tell patient that people over age 40 need to have eye examinations every two years to screen for conditions that may develop without awareness (e.g., glaucoma).
- Tell patient that people with diabetes or over age 65 should have yearly eye examinations.
- Describe the typical symptoms of eye disease (see Box 31-13).
- Instruct older adult to take the following precautions because of normal visual changes: avoid or use caution while driving at night, increase lighting in the home to reduce risk of falls, and paint the first and last steps of a staircase and the edge of each step in between a bright colour to aid depth perception.

Evaluation

- Ask patient or family member to report on patient's most recent visit to an ophthalmologist.
- Have patient describe when to have an eye examination.
- Ask patient to describe common symptoms of eye disease.
- Observe the home environment of a patient with visual deficits.

Reference: Agency for Healthcare Research and Quality. (2005). *Guide to clinical preventive services* (AHRQ Publication No. 05-0570). Rockville, MD: Author. Retrieved from <http://www.ahrp.gov/clinic/pocketgd.htm>.

patient's hearing acuity. External ear structures consist of the auricle, outer ear canal, and tympanic membrane (eardrum). The ear canal is normally curved and approximately 2.5 cm long in an adult. It is lined with skin containing fine hairs, nerve endings, and glands secreting **cerumen**. The middle ear is an air-filled cavity containing the three bony ossicles (malleus, incus, and stapes). The eustachian tube connects the middle ear to the nasopharynx. Pressure between the outer atmosphere and the middle ear is stabilized through the eustachian tube.

The inner ear contains the cochlea, vestibule, and semicircular canals. Assessing the ears determines the integrity of ear structures and the condition of hearing. Nursing history data (Table 31-14) aid in identifying risks for hearing disorders.

Understanding the mechanisms for sound transmission helps identify the nature of hearing disorders. Sound travels through the ear by air and bone conduction; the following explains the steps of hearing:

1. Sound waves in the air enter the external ear, passing through the outer ear canal.
2. The sound waves reach the tympanic membrane, causing it to vibrate.
3. Vibrations are transmitted through the middle ear by the bony ossicular chain to the oval window at the opening of the inner ear.
4. The cochlea receives the sound vibration.

BOX 31-15 PATIENT TEACHING

Ear Assessment

Objectives

- Patient uses proper technique for cleansing the ears.
- Patient follows preventive guidelines for screening of hearing loss.
- Patient with hearing loss communicates effectively.

Teaching Strategies

- Instruct patient in the proper way to clean the outer ear (see Chapter 37), avoiding use of cotton-tipped applicators and sharp objects such as hairpins, which cause impaction of cerumen deep in the ear canal or cause trauma.
- Tell patient to avoid inserting pointed objects into the ear canal.
- Encourage patients over age 65 to have regular hearing checks. Explain that a reduction in hearing is a normal part of aging (see Chapter 47).
- Instruct family members of patients with hearing losses to avoid shouting and instead speak in low tones, and to be sure the patient is able to see the speaker's face.

Evaluation

- Ask patient to explain the proper technique for cleansing the ears.
- In a follow-up visit, question patient about frequency of hearing checks.
- Observe patient with hearing loss interacting with family members.

Figure 31-15 Structures of the external, middle, and inner ear.

5. Nerve impulses from the cochlea travel to the auditory (eighth cranial) nerve and to the cerebral cortex.

Disorders of the ear result from several types of problems, including mechanical dysfunction (blockage by earwax or foreign body), trauma (foreign bodies or noise exposure), neurological disorders (auditory nerve damage), acute illnesses (viral infection), and toxic effects of medications.

Auricles. With the patient sitting comfortably, inspect the auricle's size, shape, symmetry, landmarks, position, and colour (Figure 31-16). The auricles are normally of equal size and level with each other. The upper point of attachment is in a straight line with the lateral canthus, or corner of the eye. The position of the auricle is almost vertical. Ears that are low

TABLE 31-14 Nursing History for Ear Assessment

Assessment Category

Rationale

Assess if patient has experienced ear pain, itching, discharge, vertigo, tinnitus (ringing in ears), or change in hearing.	These signs and symptoms indicate infection or hearing loss.
Assess risks for hearing problem.	Risk factors predispose patient to permanent hearing loss.
<i>Infants/children:</i> Hypoxia at birth, meningitis, birth weight less than 1500 g, family history of hearing loss, congenital anomalies of skull or face, nonbacterial intrauterine infections (rubella, herpes), maternal drug use, excessively high bilirubin, head trauma	It is difficult to assess infant's hearing status with examination only.
<i>Adults:</i> Exposure to industrial or recreational noise, genetic disease (Meniere disease), neurodegenerative disorder	
Determine patient's exposure to loud noises at work and availability of protective devices.	Prolonged noise exposure causes temporary or permanent hearing loss.
Note behaviours indicative of hearing loss, such as failure to respond when spoken to, requests to repeat comments, leaning forward to hear, and child's inattentiveness or use of monotonous voice tone.	Individuals with hearing loss cope with sensory deficit through a variety of behavioural cues.
Assess if patient takes large doses of aspirin or other ototoxic drugs (e.g., aminoglycosides, furosemide, streptomycin).	Medications have side effects of hearing loss.
Determine whether patient uses hearing aid.	Determination allows nurse to assess ability to care for device and allows nurse to adjust voice tone to communicate.
If patient had recent hearing problem, note onset, contributing factors, affected ear, and effect on activities of daily living.	Helps determine nature and severity of hearing problem.
Determine whether patient has repeated history of cerumen buildup in ear.	Cerumen impaction is common cause for conduction deafness.

set or at an unusual angle are a sign of chromosome abnormality (e.g., Down syndrome) or may indicate the possibility of fetal alcohol affects/syndrome. Ear colour is usually the same as that of the face, without moles, cysts, deformities, or nodules. Redness is a sign of inflammation or fever. Extreme pallor indicates frostbite. Deformities of the ear can be a sign that there may be other organ abnormalities that occurred during fetal development (e.g., kidney).

Palpate the auricles for texture, tenderness, and skin lesions. Auricles are normally smooth and without lesions. If the patient complains of pain, gently pull the auricle, press on the tragus, and palpate behind the ear over the mastoid process. If palpating the external ear increases the pain, an external

Figure 31-16 Anatomical structures of the auricle. **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 298). St Louis, MO: Mosby.

ear infection is likely. If palpation of the auricle and tragus does not influence the pain, the patient possibly has a middle ear infection. Tenderness in the mastoid area indicates mastoiditis.

Inspect the opening of the ear canal for size and presence of discharge. If discharge is present, wear clean gloves during the examination. A swollen or occluded meatus is not normal. A yellow, waxy substance called cerumen is common. Yellow or green, foul-smelling discharge indicates infection or a foreign body.

Ear Canals and Eardrums. Deeper structures of the external and middle ear are assessed with the use of an **otoscope**. The examination of the internal ear structures through the use of an otoscope is beyond the scope of new graduate nurses' practice. Advanced nurse practitioners use the otoscope to inspect the ear canal, tympanic membrane, and bony landmarks. Patients in greatest need of an examination are those with a possible foreign body in the ear canal, pain, swelling, or injury near the ear or patients with disorders related to balance. A detailed presentation of an otoscope examination of the inner ear can be found in Jarvis et al., (2009), *Physical Examination and Health Assessment*, First Canadian Edition.

Hearing Acuity. A patient with a hearing loss often fails to respond to conversation. The three types of hearing loss are conduction, sensorineural, and mixed. A conduction loss interrupts sound waves as they travel from the outer ear to the cochlea of the inner ear because the sound waves are not transmitted through the outer and middle ear structures. Examples of causes of a conduction loss are swelling of the auditory canal or tears in the tympanic membrane. A sensorineural loss involves the inner ear, auditory nerve, or hearing centre of the brain. Sound is conducted through the outer and middle ear structures, but the continued transmission of sound becomes interrupted at some point beyond the bony ossicles. A mixed loss involves a combination of conduction and sensorineural loss.

safety alert Patients working or living around loud noises are at risk for hearing loss. In addition, adolescents are at risk for premature hearing loss from continued exposure to loud music in their car or home or at concert events. The use of iPods and MP3 players also increases the risk for hearing loss in all patients.

Older adults experience an inability to hear high-frequency sounds and consonants (e.g., S, Z, T, and G). Deterioration of the cochlea and thickening of the tympanic membrane cause older adults to gradually lose hearing acuity. They are especially at risk for hearing loss due to **ototoxicity** (injury to auditory nerve) resulting from high-maintenance doses of antibiotics (e.g., aminoglycosides).

To conduct a hearing assessment, have the patient remove any hearing aid if worn. Note the patient's response to questions. Normally, the patient responds without excessive requests to have the questions repeated. If you suspect hearing loss, check the patient's response to the whispered voice. Test one ear at a time while the patient occludes the other ear with a finger. Ask the patient to gently move the finger up and down during the test. While standing 30 to 60 cm from the testing ear, cover the mouth so that the patient is unable to read lips. After exhaling fully, whisper softly toward the unoccluded ear, reciting random numbers with equally accented syllables, such as *nine-four-ten*. If necessary, gradually increase voice intensity until the patient correctly repeats the numbers. Then test the other ear for comparison. Seidel et al. (2011) report that patients normally hear numbers clearly when whispered, responding correctly at least 50% of the time.

If a hearing loss is present, there are tests that you perform using a tuning fork or audiometry. A tuning fork of 256 to 512 hertz (Hz) is most commonly used. The tuning fork allows for comparison of hearing by bone conduction with that of air conduction. Hold the base of the tuning fork with one hand without touching the tines. Tap the fork lightly against the palm of the other hand to set the fork in vibration (Table 31-15).

Nose and Sinuses

Assess the integrity of the nose and sinuses by using inspection and palpation. The patient sits during the examination. A penlight allows for gross examination of each naris. A more detailed examination requires use of a nasal speculum to inspect the deeper nasal turbinates. Do not use a speculum unless a qualified practitioner is present. Table 31-16 lists components of the nursing history.

Nose. When inspecting the external nose, observe for shape, size, skin, colour, and the presence of deformity or inflammation. The nose is normally smooth and symmetric with the same colour as the face. Recent trauma sometimes causes edema and discolouration. If swelling or deformities exist, gently palpate the ridge and soft tissue of the nose by placing one finger on each side of the nasal arch and gently moving the fingers from the nasal bridge to the tip. Note any tenderness, masses, or underlying deviations. Nasal structures are usually firm and stable.

Air normally passes freely through the nose when a person breathes. To assess patency of the nares, place a finger on the side of the patient's nose and occlude one naris. Ask the patient to breathe with the mouth closed. Repeat the procedure for the other naris.

While illuminating the anterior nares, inspect the mucosa for colour, lesions, discharge, swelling, and evidence of

bleeding. If discharge is present, apply gloves. Normal mucosa is pink and moist without lesions. Pale mucosa with clear discharge indicates allergy. A mucoid discharge indicates rhinitis. A sinus infection results in yellowish or greenish discharge. Habitual use of intranasal cocaine and opioids causes puffiness and increased vascularity of the nasal mucosa. For the patient with a nasogastric tube, routinely check for local

skin breakdown (**excoriation**) of the naris, characterized by redness and skin sloughing.

To view the septum and turbinates, have the patient tip the head back slightly to provide a clear view. Illuminate the septum and observe for alignment, perforation, or bleeding. Normally the septum is close to the midline, and thicker anteriorly than posteriorly. The turbinates are covered with mucous

► **TABLE 31-15** Tuning Fork Tests

Tests and Steps

Weber Test (Lateralization of Sound)

Hold fork at its base and tap it lightly against heel of palm.

Place base of vibrating fork on midline vertex of patient's head or middle of forehead (see illustration below).

Ask patient if he or she hears the sound equally in both ears or better in one ear.

Rinne Test (Comparison of Air and Bone Conduction)

Place stem of vibrating tuning fork against patient's mastoid process (see illustration below).

Begin counting the interval with your watch.

Rationale

Patient with normal hearing hears sound equally in both ears. In conduction deafness, sound is heard best in impaired ear. In unilateral sensorineural hearing loss, sound is identified only in normal ear.

Patient should hear air-conducted sound twice as long as bone-conducted sound (2:1 ratio). For example, if patient hears bone-conducted sound for 10 seconds, he or she should hear air-conducted sound for an additional 10 seconds. In conduction deafness, patient can no longer hear bone-conducted sound. In sensorineural loss, sound is reduced and heard longer through air but less than 2:1 ratio.

► TABLE 31-15 Tuning Fork Tests—cont'd

Tests and Steps

Ask patient to tell you when he or she no longer hears the sound; note number of seconds. Quickly place still-vibrating tines 1 to 2 cm from ear canal, and ask patient to tell you when he or she no longer hears the sound (see illustration below).

Continue counting time the sound is heard by air conduction. Compare number of seconds the sound is heard by bone conduction versus air conduction.

Rationale

Illustrations from Seidel, H. M., Ball, J. W., Dains, J. E., Flynn, J. A., Solomon, B. S., & Stewart, R.W. (2011). *Mosby's guide to physical examination* (7th ed., p. 311). St Louis, MO: Mosby.

► TABLE 31-16 Nursing History for Nose and Sinus Assessment

Assessment Category

Ask if patient has had trauma to nose.

Ask if patient has history of allergies, nasal discharge, epistaxis (nosebleeds), or postnasal drip.

If there is history of nasal discharge, assess colour, amount, odour, duration, and associated symptoms (e.g., sneezing, nasal congestion, obstruction, or mouth breathing).

Assess for history of nosebleed, including site, frequency, amount of bleeding, treatment, and difficulty stopping bleeding.

Ask if patient uses nasal spray or drops, including amount, frequency, and duration of use.

Ask if patient snores at night or has difficulty breathing.

Rationale

Trauma causes septal deviation and asymmetry of external nose.

History is useful in determining source or nature of nasal and sinus drainage.

Aids in ruling out presence of infection, allergy, or drug use.

Characteristics sometimes reveal trauma, medication use, or excessive dryness as causative factors.

Overuse of over-the-counter nasal preparations causes physical change in mucosa.

Difficulty with breathing or snoring indicates septal deviation or obstruction.

**Figure 31-17** Palpation of maxillary sinuses.

membranes that warm and moisten inspired air. Normal mucosa is pink and moist, without lesions. A deviated septum obstructs breathing and interferes with passage of a nasogastric tube. Perforation of the septum often occurs after repeated use of intranasal cocaine. Note any **polyps** (tumourlike growths) or purulent drainage.

Sinuses. Examination of the sinuses involves palpation. In cases of allergies or infection, the interior of the sinuses become inflamed and swollen. The most effective way to assess for tenderness is by externally palpating the frontal and maxillary facial areas (Figure 31-17). Palpate the frontal sinus

BOX 31-16 PATIENT TEACHING

Nose and Sinus Assessment

Objectives

- Patient will safely use over-the-counter nasal sprays.
- Parents will take proper measures to stop a child's nosebleed.
- Older adult will take safety precautions with loss of olfaction.

Teaching Strategies

- Caution patient against overuse of over-the-counter nasal sprays, which leads to "rebound" effect, causing excess nasal congestion.
- Instruct parents in care of a child with nosebleeds: have child sit up and lean forward to avoid aspiration of blood, apply pressure to the anterior nose with the thumb and forefinger as the child breathes through the mouth, and apply ice or a cold cloth to the bridge of the nose if pressure fails to stop bleeding.
- Instruct older adults to install smoke detectors on each floor of their home.
- Instruct older adults to always check dated labels on food to ensure against spoilage.

Evaluation

- Have patient explain proper use of over-the-counter nasal sprays.
- Have parents demonstrate and describe technique for stopping a nosebleed.
- Inspect patient's home during visit, and look for smoke detectors. Ask to check some food items in the refrigerator.

by exerting pressure with the thumb up and under the patient's eyebrow. Gentle, upward pressure elicits tenderness easily if sinus irritation is present. Do not apply pressure to the eyes. If tenderness of sinuses is present, the sinuses may be transilluminated. This procedure, however, requires advanced experience. Box 31-16 describes teaching guidelines during nose and sinus assessment.

Mouth and Pharynx

Assess the mouth and pharynx to detect signs of overall health, determine oral hygiene needs, and develop therapies for patients with dehydration, restricted intake, oral trauma, or oral airway obstruction. To assess the oral cavity, use a penlight and tongue depressor or a single gauze square. Wear clean gloves during the examination. Have the patient sit or lie down during the examination. Assess the oral cavity also while administering oral hygiene (see Chapter 37). Table 31-17 describes the nursing history for assessment of the mouth and pharynx.

Lips. Inspect the lips for colour, texture, hydration, contour, and lesions. With the patient's mouth closed, view the lips from end to end. Normally they are pink, moist, symmetrical, and smooth (Figure 31-18). Lip colour in the dark-skinned patient varies from pink to plum. Have female patients (especially older adults) remove their lipstick before the examination. Anemia causes pallor of the lips, with cyanosis caused by respiratory or cardiovascular problems. Cherry-coloured lips indicate carbon monoxide poisoning. Any lesions such as nodules or ulcerations are related to infection, irritation, or skin cancer.

Buccal Mucosa, Gums, and Teeth. Ask the patient to clench the teeth and smile to observe teeth occlusion. The

TABLE 31-17

Nursing History for Mouth and Pharyngeal Assessment

Assessment Category

Determine if patient wears dentures or retainers and if they are comfortable.

Determine if patient has had recent change in appetite or weight.

Determine if patient uses tobacco products:

Smoking of cigarette, cigar, or pipe

Smokeless tobacco: use of chewing tobacco and snuff

Review history for alcohol consumption.

Assess dental hygiene practices, including use of fluoride toothpaste, frequency of brushing and flossing, and frequency of dental visits.

Ask if patient has pain from chewing or eating. If so, ask if mouth lesions are present, including duration and associated symptoms.

Rationale

Patient needs to remove dentures to visualize and palpate gums.

Ill-fitting dentures chronically irritate mucosa and gums.

Symptoms result from painful mouth conditions or poor hygiene.

Smoking of these products increases risk for lung, oral cavity, larynx, and esophageal cancers (Canadian Cancer Society Steering Committee [CCS], 2010).

Smokeless tobacco causes various cancers and noncancerous oral disorders. Long-term snuff users have increased risk for cancer of the gums and cheeks (CCS, 2010).

Excessive alcohol consumption appears to have greater risk for oral cavity and pharynx cancer. Effects of alcohol are independent of tobacco use.

Assessment reveals patient's need for education and/or financial support. Periodontal disease has a higher prevalence in older adults who have history of high plaque buildup, use tobacco, and visit the dentist infrequently.

Pain is often associated with broken tooth, tooth grinding, or temporomandibular joint problems. Extra care is needed during oral hygiene administration.

Figure 31-18 The lips are normally pink, symmetrical, smooth, and moist.

BOX 31-17 PATIENT TEACHING

Mouth and Pharyngeal Assessment

Objectives

- Patient will practise proper oral hygiene measures and dental care.
- Patient will describe warning signs of oral cancer.
- Older adult will maintain normal solid food intake.

Teaching Strategies

- Discuss proper techniques for oral hygiene, including brushing and flossing (see Chapter 37).
- Explain the early warning signs of oral cavity and pharynx cancer, including a sore that bleeds easily and does not heal, a lump or thickening, and a red or white patch on the mucosa that persists. Difficulty chewing, swallowing, or moving the tongue or jaw are late symptoms (Canadian Cancer Society, 2012c).
- Encourage regular dental examination every six months for children, adults, and older adults.
- Identify older patients who have difficulty in chewing and changes in the teeth. Teach patients to eat soft foods and cut food into small pieces.

Evaluation

- Ask patient to demonstrate brushing.
- Have patient identify when to have regular dental checkups.
- Have patient identify the warning signs of oral cavity and pharynx cancer.
- Ask older adult to keep a diet record for three days.

Figure 31-19 Inspection of inner oral mucosa of the lower lip.

Figure 31-20 Retraction of the buccal mucosa allows for clear visualization.

upper molars normally rest directly on the lower molars, and the upper incisors slightly override the lower incisors. A symmetrical smile reveals normal facial nerve function.

Inspect the teeth to determine the quality of dental hygiene (Box 31-17). Note the position and alignment of the teeth. To examine the posterior surface of the teeth, have the patient open the mouth with the lips relaxed. Use a tongue depressor to retract the lips and cheeks, especially when viewing the molars. Note the colour of teeth and presence of dental **caries** (cavities), tartar, and extraction sites. Normal, healthy teeth are smooth, white, and shiny. A chalky white discolouration of the enamel is an early indication of caries formation. Brown or black discolourations indicate the formation of caries. A stained yellow colour is from tobacco use, whereas coffee, tea, and colas cause a brown stain. In the older adult, loose or missing teeth are common because bone resorption increases. An older adult's teeth often feel rough when tooth enamel calcifies. Yellow or darkened teeth are also common in the older adult because of the general wear and tear that exposes the darker, underlying dentin.

To view the mucosa and gums, ask the patient to first remove any dental appliance. View the inner oral mucosa by having the patient open and relax the mouth slightly and then gently retract the patient's lower lip away from the teeth (Figure 31-19). Repeat this process for the upper lip. Inspect the mucosa for colour, hydration, texture, and lesions such as ulcers, abrasions, or cysts. Normally the mucosa is a glistening pink, smooth, and moist. Some common small, yellow-white raised lesions on the buccal mucosa and lips are Fordyce spots, or ectopic sebaceous glands (Seidel et al., 2011). If lesions are present, palpate them gently with a gloved hand for tenderness, size, and consistency.

To inspect the buccal mucosa, ask the patient to open the mouth and then gently retract the cheeks with a tongue depressor or gloved finger covered with gauze (Figure 31-20). View the surface of the mucosa from right to left and top to bottom. A penlight illuminates the most posterior portion of the mucosa. Normal mucosa is glistening, pink, soft, moist, and smooth. Varying shades of hyperpigmentation are normal in 10% of light-skinned patients after age 50 and up to 90% of dark-skinned patients by the same age. For patients with normal pigmentation, the buccal mucosa is a good site to inspect for jaundice and pallor. In older adults, the mucosa is normally dry because of reduced salivation. Thick white patches (**leukoplakia**) are often a precancerous lesion seen in heavy smokers and alcoholics. Palpate for any buccal lesions by placing the index finger within the buccal cavity and the thumb on the outer surface of the cheek.

safety alert Patients who smoke cigarettes, cigars, or pipes and those who use smokeless tobacco have an increased risk of oral, laryngeal, and esophageal cancer. These individuals have leukoplakia or other lesions anywhere in their oral cavity (e.g., lips, gums, tongue) at an early age.

Inspect the gums (gingivae) for colour, edema, retraction, bleeding, and lesions while retracting the cheeks. Healthy gums are pink, smooth, and moist and tightly fit around each tooth. Dark-skinned patients often have patchy pigmentation. In older adults, the gums are usually pale. Using clean gloves,

Figure 31-21 The undersurface of the tongue is highly vascular.

Figure 31-22 The hard palate is located anteriorly in the roof of the mouth.

palpate the gums to assess for lesions, thickening, or masses. Normally there is no tenderness. Spongy gums that bleed easily indicate periodontal disease and vitamin C deficiency. If the patient has loose or mobile teeth, swollen gums, or pockets containing debris at the tooth margins, suspect periodontal disease or gingivitis.

Tongue and Floor of Mouth. Carefully inspect the tongue on all sides, as well as the floor of the mouth. Have the patient relax the mouth and stick the tongue out halfway. Note any deviation, tremor, or limitation in movement. This tests hypoglossal nerve function. If the patient protrudes the tongue too far, this will elicit the gag reflex. When the tongue protrudes, it lies midline. To test for tongue mobility, ask the patient to raise the tongue up and move it from side to side. The tongue should move freely.

Using a penlight for illumination, examine the tongue for colour, size, position, texture, and coatings or lesions. A normal tongue is medium or dull red in colour, moist, slightly rough on the top surface, and smooth along the lateral margins. The undersurface of the tongue and the floor of the mouth are highly vascular (Figure 31-21). Take extra care to inspect this area, a common site for oral cancer lesions. The patient lifts the tongue by placing its tip on the palate behind the upper incisors. Inspect for colour, swelling, and lesions such as nodules or cysts. The ventral surface of the tongue is pink and smooth, with large veins between the frenulum folds. To palpate the tongue, explain the procedure and ask the patient to protrude the tongue. Grasp the tip with a gauze square and gently pull it to one side. With a gloved hand, palpate the full length of the tongue and the base for any areas of hardening or ulceration. **Varicosities** (swollen, tortuous veins) are common in the older adult and rarely cause problems.

Palate. Have the patient extend the head backward, holding the mouth open to inspect the hard and soft palates. The hard palate, or roof of the mouth, is located anteriorly. The whitish hard palate is dome shaped. The soft palate extends posteriorly toward the pharynx. It is normally light pink and smooth. Observe the palates for colour, shape, texture, and extra bony prominences or defects (Figure 31-22). A bony growth, or **exostosis**, between the two palates is common.

Pharynx. Perform an examination of pharyngeal structures to rule out infection, inflammation, or lesions. Have the patient tip the head back slightly, open the mouth wide, and say “Ah” while you place the tip of a tongue depressor on the middle third of the tongue. Take care not to press the lower lip

Figure 31-23 A penlight and tongue depressor allow the visualization of the uvula and posterior soft palate.

against the teeth. By placing the tongue depressor too far anteriorly, the posterior part of the tongue mounds up, obstructing the view. Placing the tongue depressor on the posterior tongue elicits the gag reflex.

With a penlight, first inspect the uvula and soft palate (Figure 31-23). Both structures, which are innervated by the tenth cranial (vagus) nerve, should rise centrally as the patient says “Ah.” Examine the anterior and posterior pillars, soft palate, and uvula. View the tonsils in the cavities between the anterior and posterior pillars and note the presence or absence of tissue. The posterior pharynx is behind the pillars. Normally, pharyngeal tissues are pink and smooth and well hydrated. Small irregular spots of lymphatic tissue and small blood vessels are normal. Note edema, petechiae (small hemorrhages), lesions, or exudate. Patients with chronic sinus problems frequently exhibit a clear exudate that drains along the wall of the posterior pharynx. Yellow or green exudate indicates infection. A patient with a typical sore throat has a red and edematous uvula and tonsillar pillars with possible presence of yellow exudate.

Neck

Assessment of the neck includes assessing the neck muscles, lymph nodes of the head and neck, carotid arteries, jugular veins, thyroid gland, and trachea (Figure 31-24). The examination of the jugular veins and carotid arteries is included under

Figure 31-24 Anatomical position of the major neck structures. Note the triangles formed by the sternocleidomastoid muscle, lower jaw, and anterior neck anteriorly and by the sternocleidomastoid muscle, trapezius muscle, and lower neck posteriorly.

the vascular system assessment. Inspect and palpate the neck to determine the integrity of the neck structures and to examine the lymphatic system. Examine the lymphatic system region by region during the assessment of body systems (head and neck, breast, genitalia, and extremities). An abnormality of superficial lymph nodes sometimes reveals the presence of an infection or malignancy. Examination of the thyroid gland and trachea also aids in ruling out malignancies. Perform this examination with the patient sitting. The sternocleidomastoid and trapezius muscles outline the areas of the neck, dividing each side of the neck into two triangles. The anterior triangle contains the trachea, thyroid gland, carotid artery, and anterior cervical lymph nodes. The posterior triangle contains the posterior lymph nodes. Table 31-18 reviews the nursing history for the head and neck examination.

Neck Muscles. First inspect the neck in the usual anatomical position, with slight hyperextension. Observe for symmetry of the neck muscles. Ask the patient to flex the neck with the chin to the chest, hyperextend the neck backward, and move the head laterally to each side and then sideways with the ear moving toward the shoulder. This tests the sternocleidomastoid and trapezius muscles. The neck normally moves without discomfort. Tests that assess muscle strength and function can be performed during assessment of the head and neck, although the description of these tests is included in the assessment of the musculoskeletal system.

Lymph Nodes. An extensive system of lymph nodes collects lymph from the head, ears, nose, cheeks, and lips (Figure 31-25). The immune system protects the body from foreign antigens, removes damaged cells from the circulation, and provides a partial barrier to growth of malignant cells within the body. Assessing the lymph nodes requires competence when caring for patients with suspected immunoincompetence, which is often linked to allergies, human immunodeficiency virus (HIV) infection, autoimmune disease (e.g., lupus erythematosus), or serious infection.

With the patient's chin raised and head tilted slightly, first inspect the area where lymph nodes are distributed and compare both sides. This position stretches the skin slightly over any possible enlarged nodes. Inspect visible nodes for

► **TABLE 31-18**

Nursing History for Neck Assessment

Assessment Category

Assess for history of recent cold or infection or enlarged lymph nodes, exposure to radiation or toxic chemicals.

If there is an enlarged lymph node, consider reviewing history of intravenous drug use, hemophilia, sexual contact with people infected with human immunodeficiency virus (HIV), history of blood transfusion, multiple and indiscriminate sexual contacts, or male with homosexual or bisexual activities.

Ask if patient has had history of neck pain with restriction in movement.

Ask if patient has had change in temperature preference (more or less clothing); swelling in neck; change in texture of hair, skin, or nails; or change in emotional stability.

Ask if patient has history of hypothyroidism or hyperthyroidism or takes thyroid medication or has a family history of thyroid disease.

Review medical history of pneumothorax (collapsed lung) or bronchial tumour.

Rationale

Colds or infections (e.g., mononucleosis) cause temporary or permanent lymph node enlargement. Lymph nodes are also enlarged in various diseases such as cancer. These are risk factors for HIV infection.

Indicates muscle strain, head injury, local nerve injury, or enlarged or swollen lymph node.

Symptoms indicative of thyroid disease.

Disease or medications influence tissue growth of gland.

Conditions place patient at risk for tracheal displacement or lateral deviation.

edema, erythema, or red streaks. Nodes are not normally visible.

Use a methodical approach to palpate the lymph nodes to avoid overlooking any single node or chain. The patient relaxes with the neck flexed slightly forward. Inspect and palpate both sides of the neck for comparison. During palpation, either face or stand to the side of the patient for easy access to all nodes. Using the pads of the middle three fingers of each hand, gently palpate in a rotary motion over the nodes (Figure 31-26). Check each node methodically in the following sequence: occipital nodes at the base of the skull, postauricular nodes over the mastoid, preauricular nodes just in front of the ear, retropharyngeal nodes at the angle of the mandible, submandibular nodes, and submental nodes in the midline behind the mandibular tip. Try to detect enlargement and note the location, size, shape, surface characteristics, consistency, mobility, tenderness, and warmth of the nodes. If the skin is mobile, move the skin over the area of the nodes. It is important to press

Figure 31-25 Palpable lymph nodes in the head and neck. **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 241). St Louis, MO: Mosby.

Figure 31-26 Supraclavicular lymph node palpation.

underlying tissue in each area and not simply move the fingers over the skin. However, if you apply excessive pressure, you will miss small nodes and destroy palpable nodes.

To palpate supraclavicular nodes, ask the patient to bend the head forward and relax the shoulders. Palpate these nodes by hooking the index and third finger over the clavicle, lateral to the sternocleidomastoid muscle. Palpate the deep cervical

* BOX 31-18 PATIENT TEACHING

Neck Assessment

Objective

- Patient takes proper preventive action if he or she notices a mass in the neck.

Teaching Strategies

- Stress importance of regular compliance with medication schedule to patients with thyroid disease.
- Instruct patient about the lymph nodes and how infection commonly causes node tenderness.
- Instruct patient to call a health care provider when he or she notices an enlarged lump or mass in the neck.
- Teach patient risk factors for HIV infection and other sexually transmitted diseases.

Evaluation

- Have patient explain when to notify a physician about a neck mass.

HIV, Human immunodeficiency virus.

nodes only with the fingers hooked around the sternocleidomastoid muscle.

Normally lymph nodes are not easily palpable. However, small, mobile, nontender nodes are common. Lymph nodes that are large, fixed, inflamed, or tender indicate a problem such as local infection, systemic disease, or neoplasm (Jarvis et al., 2009) (Box 31-18). When you find enlarged nodes, explore the adjacent areas and regions drained by the nodes. Tenderness almost always indicates inflammation. A problem involving a lymph node of the head and neck means an abnormality in the mouth, throat, abdomen, breasts, thorax, or arms. These are the areas drained by the head and neck nodes.

Thyroid Gland. The thyroid gland lies in the anterior lower neck, in front of and to both sides of the trachea. The gland is fixed to the trachea with the isthmus overlying the trachea and connecting the two irregular, cone-shaped lobes (Figure 31-27). Inspect the lower neck overlying the thyroid gland for obvious masses, symmetry, and any subtle fullness at the base of the neck. Ask the patient to hyperextend the neck, which helps tighten the skin for better visualization. Offer the patient a glass of water, and, while observing the neck, have the patient swallow. This manoeuvre helps to visualize an abnormally enlarged thyroid. Normally you cannot visualize the thyroid.

More experienced nurses examine the thyroid by palpating for more subtle masses; this technique will not be discussed here.

Figure 31-27 Anatomical position of the thyroid gland.

Carotid Artery and Jugular Vein. This portion of the examination is described under examination of the vascular system (see later section).

Trachea. The trachea is a part of the upper respiratory system that you directly palpate. It is normally located in the midline above the suprasternal notch. Masses in the neck or mediastinum and pulmonary abnormalities cause displacement laterally. Have the patient sit or lie down during palpation. Determine the position of the trachea by palpating at the suprasternal notch, slipping the thumb and index fingers to each side. Note if the finger and thumb shift laterally. Do not apply forceful pressure because this elicits coughing.

Thorax and Lungs

Accurate physical assessment of the thorax and lungs requires review of the ventilatory and respiratory functions of the lungs. If disease is affecting the lungs, this will affect other body systems as well. For example, reduced oxygenation causes changes in mental alertness because of the brain's sensitivity to lowered oxygen levels. You will use data from all body systems to determine the nature of pulmonary alterations.

Before assessing the thorax and lungs, be familiar with the landmarks of the chest (Figure 31-28). These landmarks help you identify findings and use assessment skills correctly. The patient's nipples, angle of Louis, suprasternal notch, costal angle, clavicles, and vertebrae are key landmarks that provide a series of imaginary lines for sign identification. Keep a mental image of the location of the lobes of the lung and the position of each rib (Figure 31-29). The proper orientation to anatomical structures ensures a thorough assessment of the anterior, lateral, and posterior thorax.

Locating the position of each rib is critical to visualizing the lobe of the lung being assessed. To begin, locate the angle of Louis at the manubriosternal junction. The angle is a visible and palpable angulation of the sternum and is the point at which the second rib articulates with the sternum. Count the

Figure 31-28 Anatomical chest wall landmarks. A, Posterior chest landmarks. B, Lateral chest landmarks. C, Anterior chest landmarks.

Figure 31-29 Anterior position of lung lobes in relation to anatomical landmarks.

Figure 31-30 Lateral position of lung lobes in relation to anatomical landmarks.

ribs and intercostal spaces (between the ribs) from this point. The number of each intercostal space corresponds with that of the rib just above it. The spinous process of the third thoracic vertebra and the fourth, fifth, and sixth ribs helps to locate the lung's lobes laterally. The lower lobes project laterally and anteriorly (Figure 31-30). Posteriorly, the tip or inferior margin of the scapula lies approximately at the level of the seventh rib (Figure 31-31). After identifying the seventh rib, count upward to locate the third thoracic vertebra, and align it with the inner borders of the scapula to locate the posterior lobes.

The examination requires the patient to be undressed to the waist, with good lighting. Assess patients at risk for pulmonary problems, such as the patient confined to bed rest or the patient with chest pain who cannot fully expand the lungs. The examination begins with the patient sitting for assessment of the posterior and lateral chest. Have the patient sit or lie down for assessment of the anterior chest. Table 31-19 reviews the nursing history for lung examination.

Posterior Thorax

Begin examination of the posterior thorax by observing for any signs or symptoms in other body systems that indicate

Figure 31-31 Posterior position of lung lobes in relation to anatomical landmarks.

pulmonary problems. Reduced mental alertness, nasal flaring, somnolence, and cyanosis are examples of signs assessed that indicate oxygenation problems. Inspect the posterior thorax by observing the shape and symmetry of the chest from the patient's back and front. Note the anteroposterior diameter. Body shape or posture significantly impairs ventilatory movement. Normally the chest contour is symmetrical, with the anteroposterior diameter one-third to one-half of the transverse, or side-to-side, diameter. A barrel-shaped chest (anteroposterior diameter equals transverse diameter) characterizes aging and chronic lung disease. Infants have an almost round shape. Congenital and postural alterations cause abnormal contours. Some patients lean over a table or splint the side of the chest because of a breathing problem. Splinting or holding the chest wall because of pain causes a patient to bend toward the side affected. Such a posture impairs ventilatory movement.

Standing at a midline position behind the patient, look for deformities, position of the spine, slope of the ribs, retraction of the intercostal spaces during inspiration, and bulging of the intercostal spaces during expiration. The scapulae are normally symmetrical and closely attached to the thoracic wall. The normal spine is straight without lateral deviation. Posteriorly, the ribs tend to slope across and down. The ribs and intercostal spaces are easier to see in a thin person. Normally, no bulging or active movement occurs within the intercostal spaces during breathing. Bulging indicates that the patient is using great effort to breathe.

Also assess the rate and rhythm of breathing (see Chapter 30). Observe the thorax as a whole. The thorax normally expands and relaxes regularly with equality of movement bilaterally. In healthy adults, the normal respiratory rates vary from 12 to 20 respirations per minute.

Palpation of the posterior thorax assesses further characteristics. Palpate the thoracic muscles and skeleton for lumps, masses, pulsations, and unusual movement. If you note pain or tenderness, avoid deep palpation. Fractured rib fragments could be displaced against vital organs. Normally the chest wall is not tender. If you find a suspicious mass or swollen area, lightly palpate it for size, shape, and the typical qualities of a lesion.

► TABLE 31-19 Nursing History for Lung Assessment

Assessment Category

Assess history of tobacco or marijuana use, including type of tobacco, duration and amount (pack-years = number of years smoked × number of packs per day), age started, and efforts to quit and length of time since smoking stopped.

Ask if patient has had a *persistent cough* (productive or nonproductive), *sputum streaked with blood*, *voice change*, *chest pain*, shortness of breath, **orthopnea**, dyspnea during exertion or at rest, poor activity tolerance, or *recurrent attacks of pneumonia or bronchitis*.

Determine if patient works or lives in an environment containing pollutants (e.g., asbestos, arsenic, coal dust) or requiring exposure to radiation. Does patient have exposure to second-hand smoke?

Review history for known or suspected human immunodeficiency virus (HIV) infection, substance abuse, low income, or being a resident or employee of nursing home or shelter, homeless, recent prison inmate, family member of tuberculosis (TB) patient, or immigrant to Canada from a country where TB is prevalent (Canadian Public Health Association, 2005).

Ask if patient has history of persistent cough, hemoptysis, unexplained weight loss, fatigue, night sweats, or fever.

Does patient have history of chronic hoarseness?

Assess history of allergies to pollens, dust, or other airborne irritants and to foods, drugs, or chemical substances.

Review family history for cancer, tuberculosis, allergies, or chronic obstructive pulmonary disease.

Ask if patient has had a pneumonia or influenza vaccine and a TB test; if not, educate patient on need to do so.

Rationale

Smoking is a risk factor for lung cancer, heart disease, cerebrovascular disease, emphysema, or chronic bronchitis. Smoking accounts for a significant percentage of all cancer deaths.

Symptoms of cardiopulmonary alterations help localize objective physical findings. (Warning signals for lung cancer are in *italic type*.)

These risk factors increase chance for various lung diseases.

These are risk factors for HIV.

These are risk factors for both tuberculosis and HIV infection.

Hoarseness indicates laryngeal disorder or abuse of cocaine or opioids (sniffing).

Symptoms such as choking feeling, bronchospasm with respiratory stridor, wheezes on auscultation, and dyspnea are often caused by allergic response. Conditions place patient at risk for lung disease.

The very young, the very old, and those with chronic respiratory problems or with immunosuppressive diseases are at increased risk for respiratory disease.

Figure 31-32 A, Hand position for palpation of posterior thorax excursion. B, As patient inhales, movement of chest excursion separates the thumbs.

To measure chest excursion or depth of breathing, stand behind the patient and place the thumbs along the spinal processes at the tenth rib, with the palms lightly contacting the posterolateral surfaces. Place thumbs 5 cm apart, pointing toward the spine and fingers pointing laterally (Figure 31-32, A). Press the hands toward the spine so that a small skin fold appears between the thumbs. Do not slide the hands over the skin. Instruct the patient to take a deep breath after exhaling. Note movement of the thumbs (Figure 31-32, B). Chest excursion is symmetrical, separating the thumbs 3 to 5 cm. Reduced chest excursions may be caused by pain, postural deformity,

or fatigue. In older adults, chest movement normally declines because of costal cartilage calcification and respiratory muscle atrophy.

During speech, the sound created by the vocal cords is transmitted through the lung to the chest wall. The sound waves create vibrations that you palpate externally. These vibrations are called **vocal fremitus** or **tactile fremitus**. Accumulation of mucus, collapse of lung tissue, or presence of lung lesions blocks the vibrations from reaching the chest wall.

To palpate for tactile fremitus, place the palmar surfaces of the fingers or the ulnar part of the hand over symmetrical

Figure 31-33 A to C, A systematic pattern (posterior-lateral-anterior) is followed when palpating and auscultating the thorax.

intercostal spaces, beginning at the lung apex (Figure 31-33, A), using a firm, light touch. Ask the patient to say “ninety-nine” or “one-one-one.” Palpate both sides simultaneously and symmetrically (from top to bottom) for comparison, or use one hand, quickly alternating between the two sides (Seidel et al., 2011). Normally a faint vibration is present as the patient speaks. If fremitus is faint, ask the patient to speak in a louder or lower tone of voice. Normally fremitus is symmetrical. Vibrations are strongest at the top, near the level of the tracheal bifurcation. You assess strong vibrations through the chest wall in a crying infant.

Auscultation assesses the movement of air through the tracheobronchial tree and detects mucus or obstructed airways. Normally, air flows through the airways in an unobstructed pattern. Recognizing the sounds created by normal airflow allows the nurse to detect sounds caused by airway obstruction.

Place the diaphragm of the stethoscope firmly on the skin, over the posterior chest wall between the ribs (Figure 31-34). The patient folds the arms in front of the chest and keeps the head bent forward while taking slow, deep breaths with the mouth slightly open. Listen to an entire inspiration and expiration at each position of the stethoscope. If sounds are faint, as in the obese patient, ask the patient to breathe harder and faster temporarily. Breath sounds are much louder in children because of their thin chest walls. In children, the bell works best because of a child’s small chest. Use a systematic pattern comparing lung sounds in one region on one side of the body with sounds in the same region on the opposite side. It is

Figure 31-34 Use the diaphragm of the stethoscope to auscultate breath sounds. **Source:** From Seidel, H. M., et al. (2011). *Mosby’s guide to physical examination* (7th ed., p. 354). St Louis, MO: Mosby.

impossible to remember the quality of all sounds noted on one side of the body and then compare them with sounds on the other side (see Figure 31-32, A).

Auscultate for normal breath sounds and abnormal or **adventitious sounds**. Normal breath sounds differ in character, depending on the area you are auscultating. You normally

► TABLE 31-20 Normal Breath Sounds

Description	Location	Origin
Vesicular Vesicular sounds are soft, breezy, and low pitched. Inspiratory phase is 3 times longer than expiratory phase.	Best heard over lung's periphery (except over scapula)	Created by air moving through smaller airways
Bronchovesicular Bronchovesicular sounds are blowing sounds that are medium pitched and of medium intensity. Inspiratory phase is equal to expiratory phase.	Best heard posteriorly between scapulae and anteriorly over bronchioles lateral to sternum at first and second intercostal spaces	Created by air moving through large airways
Bronchial Bronchial sounds are loud and high pitched with hollow quality. Expiration lasts longer than inspiration (3:2 ratio).	Heard only over trachea	Created by air moving through trachea close to chest wall

hear bronchovesicular and vesicular sounds over the posterior thorax (Table 31-20).

Abnormal sounds result from air passing through moisture, mucus, or narrowed airways. They also result from alveoli suddenly reinflating or from an inflammation between the pleural linings of the lung. Adventitious sounds often occur superimposed over normal sounds. The four types of adventitious sounds are crackles, rhonchi, wheezes, and pleural friction rub. A specific entity causes each sound, and each has typical auditory features (Table 31-21). During auscultation note the location and characteristics of the sounds, and listen for the absence of breath sounds (found in patients with collapsed or surgically removed lobes).

If there are abnormalities in tactile fremitus or auscultation, perform the vocal resonance tests (spoken and whispered voice sounds). Place the stethoscope over the same locations used to assess breath sounds, and have the patient say “ninety-nine” in a normal voice tone. Normally, the sound is muffled. If fluid is compressing the lung, the vibrations from the patient’s voice are transmitted to the chest wall and the sound becomes clear (**bronchophony**). Then ask the patient to whisper “ninety-nine.” The whispered voice is usually faint and indistinct. Certain lung abnormalities cause the whispered voice to become clear and distinct (**whispered pectoriloquy**). Bronchophony and whispered pectoriloquy can be indicative of lung disorders such as pneumonia, asthma, chronic obstructive pulmonary disease (COPD), and lung tumours and suggest the need for diagnostic assessment.

Lateral Thorax

Extend the assessment of the posterior thorax to the lateral sides of the chest. The patient sits during examination of the lateral chest. Have the patient raise the arms, to improve access to lateral thoracic structures. Use inspection, palpation, and auscultation skills to examine the lateral thorax (see Figure 31-33, B). Do not assess excursion laterally. Normally, the breath sounds you hear are vesicular.

Anterior Thorax

Inspect the anterior thorax for the same features as the posterior thorax. The patient sits or lies down with the head elevated (Box 31-19). Observe the accessory muscles of breathing: sternocleidomastoid, trapezius, and abdominal muscles. The accessory muscles move little with normal passive breathing.

When an adult patient requires effort to breathe as a result of strenuous exercise or disease (e.g., COPD), the accessory muscles and abdominal muscles contract. Some patients produce a grunting sound. In children, an increased effort to breathe can cause an increased use of accessory muscles of the neck and chest, resulting in nasal flaring, tracheal tug (indrawing of the suprasternal area), and chest wall retractions. Children sometimes produce an audible wheeze or barking sounds.

Observe the width of the costal angle. It is usually larger than 90 degrees between the two costal margins. Observe the breathing pattern. Normal breathing is quiet and barely audible near the open mouth. You most often assess respiratory rate and rhythm anteriorly (see Chapter 30). The male patient’s respirations are usually diaphragmatic, whereas a female’s are more costal. Accurate assessment occurs as a patient breathes passively.

Palpate the anterior thoracic muscles and skeleton for lumps, masses, tenderness, or unusual movement. The sternum and xiphoid are relatively inflexible. Place the thumbs parallel along the costal margin approximately 6 cm apart with the palms touching the anterolateral chest. Push the thumbs toward the midline to create a skin fold. As the patient inhales deeply, the thumbs normally separate approximately 3 to 5 cm, with each side expanding equally.

Assess tactile fremitus over the anterior chest wall. Anterior findings differ from posterior findings because of the heart and female breast tissue. You feel fremitus next to the sternum at the second intercostal space, at the level of the bronchial bifurcation. It decreases over the heart, lower thorax, and breast tissue.

Auscultation of the anterior thorax follows a systematic pattern (see Figure 31-33, C). Have the patient sit, if possible, to maximize chest expansion. Give special attention to the lower lobes, where mucous secretions commonly gather. Listen for bronchovesicular and vesicular sounds above and below the clavicles and along the lung periphery. Auscultate also for bronchial sounds, which are loud, high pitched, and hollow sounding, with expiration lasting longer than inspiration (3:2 ratio). You normally hear this sound over the trachea.

Use a systematic pattern when comparing the right and left sides (see Figure 31-34). Initially, you may want to auscultate all of the left side and then return to the right side. This is

► TABLE 31-21 Adventitious Breath Sounds

Sound	Site Auscultated	Cause	Character
Crackles 	Are most common in dependent lobes: right and left lung bases	Random, sudden reinflation of groups of alveoli; disruptive passage of air through small airways	Fine crackles are high-pitched fine, short, interrupted crackling sounds heard during end of inspiration, usually not cleared with coughing. Medium crackles are lower, more moist sounds heard during middle of inspiration; not cleared with coughing. Coarse crackles are loud, bubbly sounds heard during inspiration; not cleared with coughing.
Rhonchi (sonorous wheeze) 	Are primarily heard over trachea and bronchi; if loud enough, you are able to hear over most lung fields	Muscular spasm, fluid, or mucus in larger airways, new growth or external pressure causing turbulence	Loud, low-pitched, rumbling coarse sounds heard most often during inspiration or expiration; sometimes cleared by coughing.
Wheezes (sibilant wheeze) 	Heard over all lung fields	High-velocity airflow through severely narrowed or obstructed airway	High-pitched, continuous musical sounds like a squeak heard continuously during inspiration or expiration; usually louder on expiration.
Pleural friction rub 	Heard over anterior lateral lung field (if patient is sitting upright)	Inflamed pleura, parietal pleura rubbing against visceral pleura	Has dry, rubbing, or grating quality heard during inspiration or expiration; does not clear with coughing; heard loudest over lower lateral anterior surface.

Data from Seidel, H. M., Ball, J. W., Dains, J. E., Flynn, J. A., Solomon, B. S., & Stewart, R. W. (2011). *Mosby's guide to physical examination* (7th ed., pp. 355–357). St Louis, MO: Mosby.

incorrect. You need to compare lung sounds in one region on one side of the body with sounds in the same region on the opposite of the body.

Heart

Compare the assessment of heart function with findings from the vascular assessment (see later section). Alterations in either system sometimes manifest as changes in the other. Some patients with signs or symptoms of heart (cardiac) problems have a life-threatening condition requiring immediate attention. In this case, act quickly and conduct only the portions of the examination that are absolutely necessary. When a patient is more stable, conduct a more thorough assessment. The nursing history (Table 31-22) provides data to help interpret physical findings.

Assess cardiac function through the anterior thorax. Form a mental image of the heart's exact location (Figure 31-35). In the adult, the heart is located in the centre of the chest

(precordium), behind and to the left of the sternum, with a small section of the right atrium extending to the right of the sternum. The base of the heart is the upper portion, and the apex is the bottom tip. The surface of the right ventricle composes most of the heart's anterior surface. A section of the left ventricle shapes the left anterior side of the apex. The apex actually touches the anterior chest wall at approximately the fourth to fifth intercostal space just medial to the left midclavicular line. This is the **apical impulse** or **point of maximal impulse (PMI)**.

An infant's heart is positioned more horizontally. The apex of the heart is at the third or fourth intercostal space, just to the left of the midclavicular line. By the age of seven, a child's PMI is in the same location as the adult's. In tall, slender individuals, the heart hangs more vertically and is positioned more centrally. With increased stockiness and shortness, the heart tends to lie more to the left and horizontally (Jarvis et al., 2009).

To assess heart function, a clear understanding of the cardiac cycle and associated physiological events is of utmost

BOX 31-19 PATIENT TEACHING

Lung Assessment

Objectives

- Patient describes warning signs of lung disease.
- Children receive routine childhood immunizations.
- Older adult receives influenza and pneumonia vaccines annually.
- Patients will verbalize an understanding of air pollutants in the home and the importance of a smoke-free environment at home and in the community.
- Patient with chronic obstructive pulmonary disease (COPD) clears airways more effectively and reports less shortness of breath.

Teaching Strategies

- Explain risk factors for chronic lung disease and lung cancer, including cigarette smoking, history of smoking for over 20 years, exposure to environmental pollution, and radiation exposure from occupational, medical, and environmental sources. Exposure to radon and asbestos also increases risk, especially for cigarette smokers. Other risk factors include certain metals (arsenic, cadmium, chromium), some organic chemicals, and tuberculosis. Exposure to second-hand cigarette smoke increases risk for nonsmokers.
- Share brochures on lung cancer from Canadian Cancer Society with patient and family.
- Discuss warning signs of lung cancer, such as a persistent cough, sputum streaked with blood, chest pains, and recurrent attacks of pneumonia or bronchitis.
- Counsel parents of young children on benefits from receiving annual influenza and routine childhood vaccinations.
- Counsel older adult on benefits from receiving annual influenza and pneumonia vaccinations because of a greater susceptibility to respiratory infection.
- Instruct patient with COPD in coughing and pursed-lip breathing exercises.
- Refer individuals at risk for tuberculosis who visit clinics or health care centres for skin testing.

Evaluation

- Have patient describe risk factors for lung disease and cancer.
- Ask patient to identify any known risks for cancer.
- Ask patient to name warning signs for cancer.
- In a follow-up visit, review patient's immunization record.
- Observe patient performing breathing exercises and coughing.

Figure 31-35 Anatomical position of the heart.

TABLE 31-22 Nursing History for Heart Assessment

Assessment Category

Determine history of smoking, alcohol intake, caffeine intake, use of prescriptive and recreational drugs, exercise habits, and dietary patterns and intake (including fat and sodium intake).

Determine if patient is taking medications for cardiovascular function (e.g., antidysrhythmias, antihypertensives) and if patient knows their purpose, dosage, and side effects.

Assess for chest pain or discomfort, palpitations, excess fatigue, cough, dyspnea, leg pain or cramps, edema of feet, cyanosis, fainting, and orthopnea. Ask if symptoms occur at rest or during exercise.

If patient reports chest pain, determine if it is cardiac in nature. Anginal pain is usually a deep pressure or ache that is substernal and diffuse, radiating to one or both arms, neck, or jaw.

Determine whether patient has a stressful lifestyle. What physical demands or emotional stress exists?

Assess family history for heart disease, diabetes, high cholesterol levels, hypertension, stroke, or rheumatic heart disease.

Ask patient about history of heart trouble (e.g., heart failure, congenital heart disease, coronary artery disease, dysrhythmias, murmurs).

Determine whether patient has preexisting diabetes, lung disease, obesity, or hypertension.

Rationale

Smoking, alcohol ingestion, cocaine use, lack of regular exercise, and intake of foods high in carbohydrates, fats, and cholesterol are risk factors for cardiovascular disease. Caffeine can cause heart dysrhythmias.

Knowledge allows nurse to assess compliance with drug therapies. Medications sometimes affect vital sign values.

These are key symptoms of heart disease. Cardiovascular function is sometimes adequate during rest but not during exercise.

Determines nature of pain and need to initiate care immediately.

Repeated exposure to stress increases risk for heart disease.

Factors increase risk for heart disease.

Knowledge reveals patient's level of understanding of condition. Preexisting condition influences examination techniques used, as well as findings to expect.

These disorders alter heart function.

importance (Figure 31-36). The heart normally pumps blood through its four chambers in a methodical, even sequence. Events on the left side occur just before those on the right. As blood flows through each chamber, the valves open and close, the pressures within the chambers rise and fall, and the chambers contract. Each event creates a physiological sign. Both sides of the heart function in a coordinated fashion.

There are two phases to the cardiac cycle: systole and diastole. During systole, the ventricles contract and eject blood

Figure 31-36 Cardiac cycle. MVC, Mitral valve closes; AVO, aortic valve opens; AVC, aortic valve closes; MVO, mitral valve opens.

from the left ventricle into the aorta and from the right ventricle into the pulmonary artery. During diastole, the ventricles relax and the atria contract to move blood into the ventricles and fill the coronary arteries.

Heart sounds occur in relation to physiological events in the cardiac cycle. As systole begins, ventricular pressure rises and closes the mitral and tricuspid valves. Valve closure causes the first heart sound (S_1), often described as “lub.” The ventricles then contract, and blood flows through the aorta and pulmonary circulation. After the ventricles empty, ventricular pressure falls below that in the aorta and pulmonary artery. This allows the aortic and pulmonic valves to close, causing the second heart sound (S_2), described as “dub.” As ventricular pressure continues to fall, it drops below that of the atria. The mitral and tricuspid valves reopen to allow ventricular filling. Rapid ventricular filling creates a third heart sound (S_3), heard more often in children and young adults. An S_3 is also an abnormality in adults over 30 years of age. A fourth heart sound (S_4) occurs when the atria contract to enhance ventricular filling. You will hear an S_4 in healthy older adults, children, and athletes, but it is not normal in adults. Because S_4 also indicates an abnormal condition, report it to a health care provider.

Inspection and Palpation

Before the examination, ensure that the patient is relaxed and comfortable. Explain the procedure to relieve the patient's anxiety. An anxious or uncomfortable patient will have mild tachycardia, which will lead to inaccurate findings.

Use the skills of inspection and palpation simultaneously. The examination begins with the patient in the supine position or with the upper body elevated 45 degrees because patients with heart disease frequently suffer shortness of breath while lying flat. Stand at the patient's right side. Do not let the patient talk, especially when auscultating heart sounds. Good lighting in the room is essential.

Direct your attention to the anatomical sites best suited for assessment of cardiac function. During inspection and palpation, look for visible pulsations and exaggerated lifts, and

Figure 31-37 Anatomical sites for assessment of cardiac function.

palpate for the apical impulse and any source of vibrations (thrills). Follow an orderly sequence, beginning with assessment of the base of the heart and moving toward the apex. First inspect the angle of Louis, which lies between the sternal body and manubrium, and feel the ridge in the sternum approximately 5 cm below the sternal notch. Slip the fingers along the angle on each side of the sternum to feel adjacent ribs. The intercostal spaces are just below each rib. The second intercostal space allows identification of each of the six anatomical landmarks (Figure 31-37). The second intercostal space on the right is the aortic area, and the left second intercostal space is the pulmonic area. You will need deeper palpation to feel the spaces in obese or heavily muscled patients. After locating the pulmonic area, move the fingers down the patient's left sternal border to the third intercostal space, called the second pulmonic area. The tricuspid area is located at the fourth or fifth intercostal space along the sternum. To find the apical or mitral area, locate the fifth intercostal space just to the left of the sternum and move the fingers laterally, to the left midclavicular line. Locate the apical area with the palm of the hand or the fingertips. Normally you feel the apical impulse as a light tap in an area 1 to 2 cm in diameter at the apex (Figure 31-38). Another landmark is the epigastric area at the tip of the sternum. You typically use it to palpate for aortic abnormalities.

Locate the six anatomical landmarks of the heart, and inspect and palpate each area. Look for the appearance of pulsations, viewing each area over the chest at an angle to the side. Normally you will not see any pulsations, except perhaps at the PMI in thin patients or at the epigastric area as a result of abdominal aorta pulsation. Use the proximal halves of the four fingers together, and then alternate this with the ball of the hand to palpate for pulsations. Touch the areas gently to allow movements to lift the hand. Normally, you will not feel any pulsations or vibrations in the second, third, or fourth intercostal spaces. Loud murmurs cause a vibration. Time palpated pulsations or vibrations and their occurrence in relation to systole or diastole by auscultating heart sounds simultaneously.

Figure 31-38 Palpation of apical pulse. **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 394). St Louis, MO: Mosby.

You should feel the apical impulse or PMI easily. If you do not find it, have the patient roll onto the left side, moving the heart closer to the chest wall. Estimate the size of the heart by noting the diameter of the PMI and its position relative to the midclavicular line. In cases of serious heart disease, the cardiac muscle enlarges, with the PMI found to the left of the midclavicular line. The PMI is sometimes difficult to find in the older adult because the chest deepens in its anteroposterior diameters. It is also difficult to find in muscular or overweight patients. You usually find an infant's PMI near the third or fourth intercostal space. It is easy to palpate because of the child's thin chest wall.

Auscultation

Auscultation of the heart detects normal heart sounds, extra heart sounds, and murmurs. Concentrate on detecting low-intensity sounds created by valve closures. To begin auscultation, eliminate all sources of room noise and explain the procedure to reduce the patient's anxiety. Follow a systematic pattern beginning at the aortic area and inching the stethoscope across each of the anatomical sites (Figure 31-39). Listen for the complete cycle ("lub-dub") of heart sounds clearly at each location. Then repeat the sequence using the bell of the stethoscope. Sometimes the patient will assume three different positions during the examination (Figure 31-39): sitting up and leaning forward (good for all areas and to hear high-pitched murmurs), supine (good for all areas), and left lateral recumbent (good for all areas; best position to hear low-pitched sounds in diastole).

Learn to identify the first (S_1) and second (S_2) heart sounds. At normal rates, S_1 occurs after the long diastolic pause and preceding the short systolic pause. S_1 is high pitched, dull in quality, and heard best at the apex. If it is difficult to hear S_1 , time it in relation to the carotid pulsation. S_2 follows the short systolic pause and precedes the long diastolic pause; you hear it best at the aortic area.

Auscultate for rate and rhythm after hearing both sounds clearly. Each combination of S_1 and S_2 or "lub-dub" counts as one heartbeat. Count the rate for one minute, and listen for the interval between S_1 and S_2 , and then the time between S_2 and

Figure 31-39 Sequence of patient positions for heart auscultation. **A,** Sitting. **B,** Supine. **C,** Left lateral recumbent. **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 394). St Louis, MO: Mosby.

the next S_1 . A regular rhythm involves regular intervals of time between each sequence of beats. There is a distinct silent pause between S_1 and S_2 . Failure of the heart to beat at regular successive intervals is a **dysrhythmia**. Some dysrhythmias are life threatening.

When assessing an irregular heart rhythm, compare apical and radial pulse rates simultaneously to determine if a pulse deficit exists. Auscultate the apical pulse first, and then immediately palpate the radial pulse (one-examiner technique). Assess the apical and radial rates at the same time when two examiners are present. When a patient has a **pulse deficit**, the radial pulse is slower than the apical pulse because

ineffective contractions fail to send pulse waves to the periphery. Report a difference in pulse rates to the health care provider immediately.

Assess for extra heart sounds at each auscultatory site. Use the bell of the stethoscope, and listen for low-pitched extra heart sounds such as S_3 and S_4 gallops, clicks, and rubs. Auscultate over all anatomical areas. S_3 , or a **ventricular gallop**, occurs just after S_2 at the end of ventricular diastole. This is due to a premature rush of blood into a ventricle that is stiff or dilated as a result of heart failure and hypertension. The combination of S_1 , S_2 , and S_3 sounds like “Ken-tuck’y-y.”

S_4 , or an atrial gallop, occurs just before S_1 or ventricular systole. The sound of an S_4 is similar to that of “Ten’es-see.” Physiologically, it is due to an atrial contraction pushing against a ventricle that is not accepting blood because of heart failure or other alterations. You hear extra heart sounds more easily with the patient lying on the left side and the stethoscope at the apical site.

The final portion of the examination includes assessment for heart murmurs. **Murmurs** are sustained swishing or blowing sounds heard at the beginning, middle, or end of the systolic or diastolic phase. They are due to increased blood flow through a normal valve, forward flow through a stenotic valve or into a dilated vessel or heart chamber, or backward flow through a valve that fails to close. A murmur is asymptomatic or a sign of heart disease (Box 31-20). Murmurs are common in children. Keep the following factors in mind when auscultating to detect murmurs:

- When you detect a murmur, auscultate the mitral, tricuspid, aortic, and pulmonic valve areas for placement in the cardiac cycle (timing), the place it is heard best (location), radiation, loudness, pitch, and quality.
- If a murmur occurs between S_1 and S_2 , it is a systolic murmur. If it occurs between S_2 and the next S_1 , it is a diastolic murmur.
- The location of a murmur is not necessarily directly over the valves. With experience, you will learn where each type of murmur is best heard. For example, you hear mitral murmurs best at the apex of the heart.
- To assess for radiation, listen over areas besides where it is heard best. You also hear murmurs over the neck or back.
- Intensity or loudness is related to the rate of blood flow through the heart or the amount of blood regurgitated. In serious murmurs, feel for a thrust or intermittent palpable sensation at the auscultation site. A **thrill** is a continuous palpable sensation like the purring of a cat. You record intensity in the following grades (Seidel et al., 2011):
Grade 1: Barely audible in a quiet room
Grade 2: Clearly audible but quiet
Grade 3: Moderately loud
Grade 4: Loud, with associated thrill
Grade 5: Very loud, thrill easily palpable
Grade 6: Louder, may be heard without stethoscope, thrill palpable and visible
- A murmur is low, medium, or high in pitch, depending on the velocity of blood flow through the valves. You hear a low-pitched murmur best with the bell of the stethoscope. If you hear it best with the diaphragm, the murmur is high pitched.

The quality of a murmur refers to its characteristic pattern and sound. A crescendo murmur starts softly and builds in loudness. A decrescendo murmur starts loudly and then becomes less intense.

BOX 31-20 PATIENT TEACHING

Heart Assessment

Objectives

- Patient describes risk factors for heart disease and takes appropriate steps to eliminate risks from lifestyle.
- Patient with risk for heart disease will seek support from appropriate caregivers.

Teaching Strategies

- Explain risk factors for heart disease, including high dietary intake of saturated fat or cholesterol, lack of regular aerobic exercise, smoking, excess weight, stressful lifestyle, hypertension, and family history of heart disease.
- Refer patient (if appropriate) to resources available for controlling or reducing risks (e.g., nutritional counselling, exercise class, stress reduction programs).
- Explain that research shows clinical benefit from reducing dietary intake of cholesterol and saturated fats. Tell patient that about 70% to 75% of saturated fatty acids come from meats, poultry, fish, and dairy products. The Canadian Heart and Stroke Foundation recommends a diet low in saturated fatty acids and high in dietary fibre (Canadian Heart and Stroke Foundation, n.d.).
- Encourage patient to have regular measurement of total blood cholesterol levels and triglycerides. Desirable levels are less than 5.2 mmol/L for cholesterol and below 2.2 mmol/L for triglycerides. You need more than one cholesterol measurement to assess the blood cholesterol level accurately. Low-density lipoprotein (LDL) cholesterol is the major component of atherosclerotic plaques. Separate measurement of LDL cholesterol is wise in a patient with high total blood cholesterol levels. In an individual with no other risk factors, lipid-lowering therapy is advised when the LDL cholesterol level is above 5.0 mmol/L or the total cholesterol to high-density lipoprotein ratio is greater than 6.0 (McPherson et al., 2006). Cardiovascular risk can be assessed using the Framingham Risk Score (D’Agostino et al., 2008).
- Advise patient to avoid cigarette smoke because nicotine causes vasoconstriction.
- Advise patient to quit smoking because this lowers the risk for coronary heart disease.
- Patients who are at risk benefit from taking a daily low dose of aspirin. Consult health care provider before starting therapy.

Evaluation

- Ask patient to identify risk factors for heart disease.
- Have patient develop a meal plan low in saturated fat and cholesterol.
- Check patient’s cholesterol level during follow-up appointments at the clinic or physician’s office.

Vascular System

Examination of the vascular system includes measuring the blood pressure (see Chapter 30) and assessing the integrity of the peripheral vascular system. Table 31-23 reviews the nursing history data collected before the examination. Use the skills of inspection, palpation, and auscultation. Perform portions of the vascular examination during other body systems assessments. For example, check the carotid pulse after palpating the cervical lymph nodes. Note signs and symptoms of arterial and venous insufficiency when assessing the skin.

► TABLE 31-23

Nursing History for Vascular Assessment

Assessment Category

Rationale

Determine if patient experiences leg cramps, numbness or tingling in extremities, sensation of cold hands or feet, pain in legs, or swelling or cyanosis of feet, ankles, or hand.

These signs and symptoms indicate vascular disease.

If patient experiences leg pain or cramping in lower extremities, ask if walking or standing for long periods or during sleep aggravates or relieves it.

Relationship of symptoms to exercise will clarify whether problem is vascular or musculoskeletal. Pain caused by vascular condition tends to increase with activity. Musculoskeletal pain is not usually relieved when exercise ends.

Ask patients if they wear tight-fitting garters or hosiery and sit or lie in bed with legs crossed.

Tight hosiery around lower extremities and crossing legs can impair venous return.

Reconsider previous heart risk factors (e.g., smoking, exercise, nutritional problems).

These predispose patient to vascular disease.

Assess medical history for heart disease, hypertension, phlebitis, diabetes, or varicose veins.

Circulatory and vascular disorders influence findings gathered during examination.

Blood Pressure

When auscultating blood pressure, know that readings between the arms vary by as much as 10 mm Hg and tend to be higher in the right arm (Jarvis et al., 2009). Always record the higher reading. Systolic readings that differ by 15 mm Hg or more suggest atherosclerosis or disease of the aorta.

Carotid Arteries

When the left ventricle pumps blood into the aorta, the arterial system transmits pressure waves. The carotid arteries reflect heart function better than peripheral arteries because their pressure correlates with that of the aorta. The carotid artery supplies oxygenated blood to the head and neck (Figure 31-40). The overlying sternocleidomastoid muscle protects it.

To examine the carotid arteries, have the patient sit or lie supine with the head of the bed elevated 30 degrees. Examine one carotid artery at a time. If both arteries are simultaneously occluded during palpation, the patient will lose consciousness as a result of inadequate circulation to the brain. Do not palpate or massage the carotid arteries vigorously because the carotid sinus is located at the bifurcation of the common carotid arteries in the upper third of the neck. This sinus sends impulses along the vagus nerve. Its stimulation causes a reflex drop in heart rate and blood pressure, which causes **syncope** or circulatory arrest. This is a particular problem for older adults.

Begin inspection of the neck for obvious pulsation of the artery. Have the patient turn the head slightly away from the

Figure 31-40 Anatomical position of the carotid artery.

Figure 31-41 Palpation of internal carotid artery along the margin of the sternocleidomastoid muscle.

artery being examined. Sometimes the wave of the pulse is visible. The carotid is the only site for assessing the quality of a pulse wave. An absent pulse wave indicates arterial **occlusion** (blockage) or **stenosis** (narrowing).

To palpate the pulse, ask the patient to look straight ahead or turn the head slightly toward the side you are examining. Turning relaxes the sternocleidomastoid muscle. Slide the tips of the index and middle fingers around the medial edge of the sternocleidomastoid muscle. Gently palpate to avoid occlusion of circulation (Figure 31-41).

The normal carotid pulse is localized rather than diffuse. As a strong pulse, the carotid has a thrusting quality. As the patient breathes, no change occurs. Rotation of the neck or a shift from a sitting to a supine position does not change the carotid artery's quality. Both carotid arteries are normally equal in pulse rate, rhythm, and strength and are equally elastic. Diminished or unequal carotid pulsations indicate **atherosclerosis** or other forms of arterial disease.

The carotid is the most commonly auscultated pulse. Auscultation is especially important for middle-aged or older adults or patients suspected of having cerebrovascular disease.

Figure 31-42 Occlusion or narrowing of the carotid artery disrupts normal blood flow. The resultant turbulence creates a sound (bruit) that is auscultated.

Figure 31-43 Auscultation for carotid artery bruit. **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 436). St Louis, MO: Mosby.

When the lumen of a blood vessel is narrowed, this disturbs blood flow. As blood passes through the narrowed section, this creates turbulence, causing a blowing or swishing sound. The blowing sound is called a **bruit** (pronounced "brew-ee") (Figure 31-42).

Place the bell of the stethoscope over the carotid artery at the lateral end of the clavicle and the posterior margin of the sternocleidomastoid muscle. Have the patient turn the head slightly away from the side being examined (Figure 31-43). Ask

the patient to hold the breath for a moment so that breath sounds do not obscure a bruit. Normally, you do not hear any sounds during carotid auscultation. Palpate the artery lightly for a thrill (palpable bruit) if you hear a bruit.

Jugular Veins

The most accessible veins for examination are the internal and external jugular veins in the neck. Both veins drain bilaterally from the head and neck into the superior vena cava. The external jugular vein lies superficially and is just above the clavicle. The internal jugular vein lies deeper, along the carotid artery.

It is best to examine the right internal jugular vein because it follows a more direct anatomical path to the right atrium of the heart. The column of blood inside the internal jugular vein serves as a manometer, reflecting pressure in the right atrium. The higher the column, the greater the venous pressure. Raised venous pressure reflects right-sided heart failure.

Normally, when a patient lies in the supine position, the external jugular vein distends and becomes easily visible. In contrast, the jugular veins normally flatten when the patient is in a sitting or standing position. Some patients with heart disease, however, have distended jugular veins when sitting.

To measure venous pressure, inspect the jugular veins. Blood volume, the capacity of the right atrium to receive blood and send it to the right ventricle, and the ability of the right ventricle to contract and force blood into the pulmonary artery all influence venous pressure. Any factor resulting in greater blood volume within the venous system results in elevated venous pressure. Assess venous pressure by using the following steps:

1. Ask the patient to lie supine with the head elevated 30 to 45 degrees (semi-Fowler's position).
2. Expose the neck and upper thorax. Use a pillow to align the head. Avoid neck hyperextension or flexion to ensure that the vein is not stretched or kinked (Figure 31-44).
3. Usually pulsations are not evident with the patient sitting up. As the patient slowly leans back into a supine position, the level of venous pulsations begins to rise above the level of the manubrium as much as 1 or 2 cm as the patient reaches a 45-degree angle. Measure venous pressure by measuring the vertical distance between the angle of Louis and the highest level of the visible point of the internal jugular vein pulsation.
4. Use two rulers. Line up the bottom edge of a regular ruler with the top of the area of pulsation in the jugular vein. Then take a centimetre ruler and align it perpendicular to the first ruler at the level of the sternal angle. Measure in centimetres the distance between the second ruler and the sternal angle (Figure 31-45).
5. Repeat the same measurement on the other side. Bilateral pressures higher than 2.5 cm are considered elevated and are a sign of right-sided heart failure. One-sided pressure elevation is due to obstruction.

Peripheral Arteries and Veins

To examine the peripheral vascular system, first assess the adequacy of blood flow to the extremities by measuring arterial pulses and inspecting the condition of the skin and nails. Next assess the integrity of the venous system. Assess the arterial pulses in the extremities to determine sufficiency of the entire arterial circulation.

Factors such as coagulation disorders, local trauma or surgery, constricting casts or bandages, and systemic diseases

Figure 31-44 Position of patient to assess jugular vein distension. **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 429). St Louis, MO: Mosby.

Figure 31-45 Measuring jugular venous pressure. **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 442). St Louis, MO: Mosby.

► **TABLE 31-24**

Indicators for Assessing Local Blood Flow

Indicator	Rationale
Systemic diseases (e.g., arteriosclerosis, atherosclerosis, diabetes)	Diseases result in changes in integrity of walls of arteries and smaller blood vessels.
Coagulation disorders (e.g., thrombosis, embolus)	Blood clot causes mechanical obstruction to blood flow.
Local trauma or surgery (e.g., contusion, fracture, vascular surgery)	Direct manipulation of vessels or localized edema impairs blood flow.
Application of constricting devices (e.g., casts, dressings, elastic bandages, restraints)	Constriction causes tourniquet effect, impairing blood flow to areas below site of constriction.

impair circulation to the extremities (Table 31-24). Discuss risk factors and ways to monitor for circulatory problems with the patient (Box 31-21).

Peripheral Arteries. Examine each peripheral artery using the distal pads of the second and third fingers. The thumb helps anchor the brachial and femoral artery. Apply firm pressure but avoid occluding a pulse. When a pulse is difficult to find, it helps to vary pressure and feel all around the pulse site. Be sure not to palpate your own pulse.

Routine vital signs usually include assessment of the rate and rhythm of the radial artery because it is easily accessible. Count the pulse for either 30 seconds or a full minute, depending on the character of the pulse. Always count an irregular pulse for 60 seconds. With palpation, normally feel the pulse wave at regular intervals. When an interval is interrupted by an early, late, or missed beat, the pulse rhythm is irregular. In emergencies, health care providers usually assess the carotid artery because it is accessible and most useful in evaluating heart activity. To check local circulatory status of tissues, palpate the peripheral arteries long enough to note that a pulse is present.

Assess each peripheral artery for elasticity of the vessel wall, strength, and equality. The arterial wall is normally elastic, making it easily palpable. After depressing the artery, it will spring back to shape when releasing the pressure. An abnormal artery is hard, inelastic, or calcified.

The strength of a pulse is a measurement of the force at which blood is ejected against the arterial wall. Some examiners use a scale rating from 0 to 4+ for the strength of a pulse (Seidel et al., 2011):

- 0 Absent, not palpable
- 1+ Pulse diminished, barely palpable
- 2+ Expected/normal
- 3+ Full pulse, increased
- 4+ Bounding pulse

Measure all peripheral pulses for equality and symmetry. Compare the left radial pulse with that of the right, and so on. Lack of symmetry indicates impaired circulation such as a localized obstruction or an abnormally positioned artery.

In the upper extremities, the brachial artery channels blood to the radial and ulnar arteries of the forearm and hand. If circulation in this artery becomes blocked, the hands will not

* BOX 31-21 PATIENT TEACHING

Vascular Assessment

Objectives

- Patient will know normal blood pressure range for age and compare it with own blood pressure readings to identify normalcy of blood pressure.
- Patient with vascular insufficiency will avoid activities that worsen circulatory status.

Teaching Strategies

- Tell patient the blood pressure reading. Explain the normal reading for the patient's age. Discuss implications of abnormalities.
- Instruct patient with risk or evidence of vascular insufficiency in the lower extremities to avoid tight clothing over the lower body or legs, to avoid sitting or standing for long periods, to walk regularly, and to elevate feet when sitting.
- Advise patient to avoid cigarette smoking because nicotine causes vasoconstriction.
- Identify patient with hypertension; they sometimes benefit from regular monitoring of blood pressure (daily, weekly, or monthly). Teach patient how to use home-monitoring kits (see Chapter 30).

Evaluation

- Ask patient to identify if blood pressure reading is within normal limits for age.
- Have patient with vascular insufficiency describe precautions to take to avoid further circulatory deficiency.
- Have patient demonstrate self-monitoring of blood pressure.

Figure 31-46 Anatomical positions of brachial, radial, and ulnar arteries.

receive adequate blood flow. If circulation in the radial or ulnar arteries becomes impaired, the hand will still receive adequate perfusion. An interconnection between the radial and ulnar arteries guards against arterial occlusion (Figure 31-46).

To locate pulses in the arm, have the patient sit or lie down. Find the radial pulse along the radial side of the forearm at the wrist. Thin individuals have a groove lateral to the flexor tendon of the wrist. Feel the radial pulse with light palpation in the groove (Figure 31-47). The ulnar pulse is on the opposite side of the wrist and feels less prominent (Figure 31-48). Palpate the ulnar pulse only when evaluating arterial insufficiency to the hand.

To palpate the brachial pulse, find the groove between the biceps and triceps muscle above the elbow at the antecubital fossa (Figure 31-49). The artery runs along the medial side of the extended arm. Palpate the artery with the fingertips of the first three fingers in the muscle groove.

The femoral artery is the primary artery in the leg, delivering blood to the popliteal, posterior tibial, and dorsalis pedis arteries (Figure 31-50). An interconnection between the posterior tibial and dorsalis pedis arteries guards against local arterial occlusion.

Find the femoral pulse with the patient lying down with the inguinal area exposed (Figure 31-51). The femoral artery runs below the inguinal ligament, midway between the symphysis pubis and the anterosuperior iliac spine. Sometimes you will use deep palpation to feel the pulse. Bimanual palpation is effective in obese patients. Place the fingertips of both hands on opposite sides of the pulse site. Feel a pulsatile sensation when the arterial pulsation pushes the fingertips apart.

The popliteal pulse runs behind the knee. Have the patient slightly flex the knee, with the foot resting on the examination

Figure 31-47 Palpation of radial pulse.

table, or assume a prone position with the knee slightly flexed (Figure 31-52). Instruct the patient to keep leg muscles relaxed. Palpate with the fingers of both hands deeply into the popliteal fossa, just lateral to the midline. The popliteal pulse is difficult to locate.

With the patient's foot relaxed, locate the dorsalis pedis pulse. The artery runs along the top of the foot in line with the groove between the extensor tendons of the great toe and first toe (Figure 31-53). To find the pulse, place the fingertips between the first and second toes and slowly move up the dorsum of the foot. This pulse is sometimes congenitally absent.

Figure 31-48 Palpation of ulnar pulse.

Figure 31-49 Palpation of brachial pulse.

Find the posterior tibial pulse on the inner side of each ankle (Figure 31-54). Place the fingers behind and below the medial malleolus (ankle bone). With the foot relaxed and slightly extended, palpate the artery.

Tissue Perfusion. The condition of the skin, mucosa, and nail beds offers useful data about the status of circulatory blood flow. Examine the face and upper extremities, looking at the colour of the skin, mucosa, and nail beds. The presence of cyanosis requires special attention. Heart disease sometimes causes central cyanosis, which indicates poor arterial oxygenation. Some characteristics of this are a bluish discolouration of the lips, mouth, and conjunctivae. Blue lips, earlobes, and nail beds are signs of peripheral cyanosis, which indicates peripheral vasoconstriction. When cyanosis is present, consult with a health care provider to have laboratory testing of oxygen saturation to determine the severity of the problem. Examination of the nails involves inspection for clubbing, a bulging of the tissues at the nail base. **Clubbing** is due to insufficient oxygenation at the periphery resulting from conditions such as chronic emphysema and congenital heart disease.

Figure 31-50 Anatomical position of femoral, popliteal, dorsalis pedis, and posterior tibial arteries.

Figure 31-51 Palpation of femoral pulse.

Inspect the lower extremities for changes in colour, temperature, and condition of the skin indicating either arterial or venous alterations (Table 31-25). This is a good time to ask the patient about any history of pain in the legs. If an arterial occlusion is present, the patient has signs resulting from an absence of blood flow. Pain will be distal to the occlusion. The *P's*—pain, pallor, pulselessness, paresthesias, and paralysis—characterize an occlusion. Venous congestion causes tissue

Figure 31-52 Palpation of popliteal pulse.

Figure 31-53 Palpation of dorsalis pedis pulse.

Figure 31-54 Palpation of posterior tibial pulse.

changes indicating an inadequate circulatory flow back to the heart.

During examination of the lower extremities, also inspect skin and nail texture; hair distribution on the lower legs, feet, and toes; the venous pattern; and scars, pigmentation, or

TABLE 31-25 Signs of Venous and Arterial Insufficiency

Assessment Criterion	Venous	Arterial
Colour	Normal or cyanotic	Pale; worsened by elevation of extremity; dusky red when extremity is lowered
Temperature	Normal	Cool (blood flow blocked to extremity)
Pulse	Normal	Decreased or absent
Edema	Often marked	Absent or mild
Skin changes	Brown pigmentation around ankles	Thin, shiny skin; decreased hair growth; thickened nails

ulcers. Palpate the legs and feet for colour and temperature. Also assess capillary refill. Measure capillary refill by blanching the nail bed with a substantial pressure for several seconds. Release the pressure, and observe the time elapsed before the nail regains its full colour. An acceptable capillary refill time is less than two seconds (Jarvis et al., 2009).

The absence of hair growth over the legs indicates circulatory insufficiency. Remember: do not confuse absence of hair on the legs with shaven legs. Also, many men have less hair around the calves from wearing tight-fitting dress socks or jeans. Chronic recurring ulcers of the feet or lower legs are a serious sign of circulatory insufficiency and require a health care provider's intervention.

Peripheral Veins. Assess the status of the peripheral veins by asking the patient to assume sitting and standing positions. Assessment includes inspection and palpation for varicosities, peripheral edema, and phlebitis. Varicosities are superficial veins that become dilated, especially when the legs are in a dependent position. They are common in older adults because the veins normally fibrose, dilate, and stretch. They are also common in people who stand for prolonged periods. Varicosities in the anterior or medial part of the thigh and the posterolateral part of the calf are abnormal.

Dependent edema around the area of the feet and ankles is a sign of venous insufficiency or right-sided heart failure. Dependent edema is common in older adults and individuals who spend a lot of time standing (e.g., waitresses, security guards, and nurses). To assess for pitting edema, use the index finger to press firmly for several seconds and then release over the medial malleolus or the shins. A depression left in the skin indicates edema. Grading 1+ through 4+ characterizes the severity of the edema (Figure 31-55).

Phlebitis is an inflammation of a vein that occurs commonly after trauma to the vessel wall, infection, immobilization, and prolonged insertion of IV catheters (see Chapter 38). Phlebitis promotes clot formation, a potentially dangerous situation because a clot within a deep vein of the leg can become dislodged and travel through the heart, causing a pulmonary embolus. To assess for phlebitis, inspect the calves for localized redness, tenderness, and swelling over vein sites. Gentle palpation of calf muscles reveals warmth, tenderness, and firmness of the muscle. Unilateral edema of the affected leg is one of the most reliable findings of phlebitis (Day, 2003). Determine if dorsiflexion of the foot (Homans' sign) causes

Figure 31-55 Assessing for pitting edema. **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 444). St Louis, MO: Mosby.

Figure 31-56 Inguinal lymph nodes. **Source:** From Seidel, H. M., et al. (2006). *Mosby's guide to physical examination* (6th ed., pp. 498–99). St Louis, MO: Mosby.

pain in the calf. However, Homans' sign is not always a reliable indicator of phlebitis and is present in other conditions (Day, 2003). Performing the Homans sign test is contraindicated in patients with deep vein thrombosis. If a clot is present, it may become dislodged from its original site during this test, resulting in a pulmonary embolism.

Lymphatic System

Assess the lymphatic drainage of the lower extremities during examination of the vascular system or during the female or male genital examination. Superficial and deep nodes drain the legs, but only two groups of superficial nodes are palpable. With the patient supine, palpate the area of the superficial inguinal nodes in the groin area (Figure 31-56). Then move the fingertips toward the inner thigh, feeling for any inferior nodes. Use a firm but gentle pressure when palpating over each lymphatic chain. Multiple nodes are not normally palpable, although a few soft, nontender nodes are not unusual. Enlarged, hardened, tender nodes reveal potential sites of infection or metastatic disease.

Breasts

It is important to examine the breasts of female and male patients. Males have a small amount of glandular tissue, a

potential site for the growth of cancer cells, in the breast. In contrast, the majority of the female breast is glandular tissue.

Female Breasts

Researchers predicted that new cases of invasive breast cancer would affect 23,200 women and 180 men in the Canada in 2010 (CCS Steering Committee, 2010). The disease is second to lung cancer as the leading cause of death in women with cancer. Early detection is the key to cure. A major responsibility for you is to teach patients health behaviours such as breast self-examination (BSE), so that men and women become knowledgeable about the normal texture and condition of their breast tissue (Box 31-22).

If the patient already performs self-examination, assess the method she uses and times she does the examination in relation to her menstrual cycle.

Older women require special attention when reviewing the need for regular BSE. Unfortunately, many older women ignore changes in their breasts, assuming that they are a part of aging. In addition, physiological factors affect the ease with which older women perform a BSE. Musculoskeletal limitations, diminished peripheral sensation, reduced eyesight, and changes in joint range of motion limit palpation and inspection abilities. It may be necessary to teach family members to perform the patient's examination.

The Canadian Cancer Society Steering Committee (2010) recommends the following guidelines for the early detection of breast cancer:

- All women need to report any breast changes to a health care provider immediately.
- Women need a clinical breast examination by a trained health care provider every two years from ages 40 to 49 years.
- Women need a clinical breast examination by a trained health care provider every two years from ages 50 to 69 years and a screening mammogram every two years.
- For women at increased risk or with a family history of breast cancer, the CCS recommends talking with the health care provider for screening options and additional testing.

The patient's history (Table 31-26) reveals normal developmental changes, as well as signs of breast disease. Because of its glandular structure, the breast undergoes changes during a woman's life. Knowing these changes (Box 31-23) allows complete and accurate assessment. Encourage both men and women to observe their breasts for changes.

Inspection. Have the patient remove the top gown or drape to allow simultaneous visualization of both breasts. Have the patient stand or sit with her arms hanging loosely at

► BOX 31-22 Breast Self-Examination

In the past, it was suggested that breast self-examination (BSE) needed to be performed once a month. Research has shown that monthly breast examinations are not as important as becoming familiar with the usual appearance and feel of your breasts. Familiarity makes it easier to notice any changes in the breast. Early discovery of a change from what is baseline is the main idea behind BSE.

If you menstruate, the best time to do BSE is two or three days after your period ends, when your breasts are least likely to be tender or swollen. If you no longer menstruate, pick a day, such as the first day of the month, to remind yourself it is time to do BSE.

Here is how to do BSE:

1. Stand before a mirror. Inspect both breasts for anything unusual, such as any discharge from the nipples, puckering, dimpling, or scaling of the skin.
The next two steps are designed to emphasize any change in the shape or contour of your breasts. As you do them, you will feel your chest muscles tighten.
2. Watching closely in the mirror, clasp hands behind your head and swing elbows forward.

3. Next, press hands firmly on hips and bow slightly toward your mirror as you pull your shoulders and elbows forward. Some women do the next part of the examination in the shower. Fingers glide over soapy skin, making it easy to appreciate the texture underneath.
4. Raise your left arm. Use three or four fingers of your right hand to explore your left breast firmly, carefully, and thoroughly. Beginning at the outer edge, press the flat part of your fingers in small circles, moving the circles slowly around the breast. Gradually work toward the nipple. Be sure to cover the entire breast. Pay special attention to the area between the breast and the armpit, including the armpit itself. Feel for any unusual lump or mass under the skin.
5. Repeat step 4 lying down. Lie flat on your back, right arm over your head and a pillow or folded towel under your right shoulder. This position flattens the breast and makes it easier to examine. Use the same circular motion described earlier.
6. Repeat on your right breast.

her sides. If possible, place a mirror in front of the patient during inspection so she sees what to look for when performing a BSE. To recognize abnormalities, the patient needs to be familiar with the normal appearance of her breasts. Describe observations or findings in relation to imaginary lines that divide the breast into four quadrants and a tail. The lines cross at the centre of the nipple. Each tail extends outward from the upper outer quadrant (Figure 31-57).

Inspect the breasts for size and symmetry. Normally, the breasts extend from the third to the sixth ribs, with the nipple at the level of the fourth intercostal space. It is common for one breast to be smaller. However, inflammation or a mass causes

a difference in size. As the woman becomes older, the ligaments supporting the breast tissue weaken, causing the breasts to sag and the nipples to lower.

Observe the contour or shape of the breasts, and note masses, flattening, retraction, or dimpling. Breasts vary in shape and can be convex, pendulous, or conical. Retraction or dimpling results from invasion of underlying ligaments by tumours. The ligaments fibrose and pull the overlying skin inward toward the tumour. Edema also changes the contour of the breasts. To bring out retraction or changes in the shape of breasts, ask the patient to assume three positions: raise arms above the head, press hands against the hips, and extend arms

► **TABLE 31-26** Nursing History for Breast Assessment

Assessment Category	Rationale
Determine if woman is over age 50; has a personal or family history of breast or ovarian cancer, early-onset menarche (before age 13), or late-age menopause (after age 52); never had children or gave birth to first child after age 30; or has used of oral contraceptives.	These are risk factors for breast cancer (Canadian Cancer Society [CCS], 2012a).
Ask if patient (both sexes) has noticed lump, thickening, pain, or tenderness of breast; discharge, distortion, retraction, or scaling of the nipple; or change in size of breast.	Potential signs and symptoms of breast cancer allow nurse to focus on specific areas of breast during assessment.
Determine patient's use of medications (oral contraceptives, digitalis, diuretics, steroids, or estrogen). Determine patient's caffeine intake.	Some medications cause nipple discharge. Hormones and caffeine cause fibrocystic changes in breast.
Determine patient's level of activity, alcoholic intake, and weight.	Breast cancer incidence rates correlate with being overweight or obese (postmenopausal), physical inactivity, use of oral contraceptives, and consumption of one or more alcoholic beverages per day (CCS, 2012a).
Ask if patient performs breast self-examination (BSE). If so, determine time of month she performs examination in relation to menstrual cycle. Have patient describe or demonstrate method used.	Nurse's role is to educate patient about breast cancer and techniques for BSE.
If patient reports a breast mass, ask about length of time since patient first noticed the lump. Does lump come and go, or is it always present? Have there been changes in the lump (e.g., size, relationship to menses), and are there associated symptoms?	Helps to determine nature of mass, (e.g., breast cancer versus fibrocystic disease).

straight ahead while sitting and leaning forward. Each manoeuvre causes a contraction of the pectoral muscles, which will accentuate the presence of any retraction.

Carefully inspect the skin for colour; venous pattern; and the presence of lesions, edema, or inflammation. Lift each breast when necessary to observe lower and lateral aspects for colour and texture changes. The breasts are the colour of neighbouring skin, and venous patterns are the same bilaterally. Venous patterns are easily visible in thin or pregnant

► **BOX 31-23** Normal Changes in the Breast During a Woman's Lifespan

Puberty (8 to 20 Years)

Tanner staging (1–5) is a method of assessment for sexual maturity of adolescents (Jarvis et al., 2009; Tanner, 1962). Breasts mature in five stages. One breast may grow more rapidly than the other. The ages at which changes occur and rate of developmental progression vary.

Stage 1 (Preadolescent)

This stage involves elevation of the nipple only.

Stage 2

The breast and nipple elevate as a small mound, and the areolar diameters enlarge.

Stage 3

There is further enlargement and elevation of the breast and areola, with no separation of contour.

Stage 4

The areola and nipple project into the secondary mound above the level of the breast (does not occur in all girls).

Stage 5 (Mature Breast)

Only the nipple projects, and the areola recedes (varies in some women).

Young Adulthood (20 to 30 Years)

Breasts reach full (nonpregnant) size. Shape is generally symmetrical. Breasts are sometimes unequal in size.

Pregnancy

Breast size gradually enlarges to two to three times the previous size. Nipples enlarge and become erect. Areolae darken, and diameters increase. Superficial veins become prominent. The nipples expel a yellowish fluid (colostrum).

Menopause

Breasts shrink. Tissue becomes softer, sometimes flabby.

Older Adulthood

Breasts become elongated, pendulous, and flaccid as a result of glandular tissue atrophy. The skin of the breasts tends to wrinkle, appearing loose and flabby.

Nipples become smaller and flatter and lose erectile ability. Nipples sometimes invert because of shrinkage and fibrotic changes.

Data from Hockenberry, M. J., & Wilson, P. (Eds.). (2007). *Wong's nursing care of infants and children* (8th ed.). St Louis, MO: Mosby; Seidel, H. M., Ball, J. W., Dains, J. E., Flynn, J. A., Solomon, B. S., & Stewart, R. W. (2011). *Mosby's guide to physical examination* (7th ed.). St Louis, MO: Mosby; and Ebersole, P., Touhy, T., Hess, P., Jett, K., & Schmidt, A. (2007). *Towards healthy aging: Human needs and nursing response* (7th ed.). Philadelphia, PA: Elsevier.

women. Women with large breasts often have redness and excoriation of the undersurfaces caused by rubbing of skin surfaces.

Inspect the nipple and areola for size, colour, shape, discharge, and the direction the nipples point. The normal areolae are round or oval and nearly equal bilaterally. Colour ranges from pink to brown. In light-skinned women, the areola turns brown during pregnancy and remains dark. In dark-skinned women, the areola is brown before pregnancy (Seidel et al.,

Figure 31-57 Quadrants of the left breast and axillary tail of Spence.
Source: From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 457). St Louis, MO: Mosby.

Figure 31-58 Anatomical position of axillary and clavicular lymph nodes.

2011). Normally, the nipples point in symmetrical directions, are everted, and have no drainage. If the nipples are inverted, ask if this has been a lifetime history. A recent inversion or inward turning of the nipple indicates an underlying growth. Rashes or ulcerations are not normal on the breast or nipples. Note any bleeding or discharge from the nipple. Clear yellow discharge two days after childbirth is common. While inspecting the breasts, explain the characteristics you see. Teach the patient the significance of abnormal signs or symptoms.

Palpation. Palpation assesses the condition of underlying breast tissue and lymph nodes. Breast tissue consists of glandular tissue, fibrous supportive ligaments, and fat. Glandular tissue is organized into lobes that end in ducts that open onto the nipple's surface. The largest portion of glandular tissue is in the upper outer quadrant and tail of each breast. Suspensory ligaments connect to skin and fascia underlying the breast to support the breast and maintain its upright position. Fatty tissue is located superficially and to the sides of the breast.

A large portion of lymph from the breasts drains into axillary lymph nodes. If cancerous lesions **metastasize** (spread), the nodes commonly become involved. Study the location of supraclavicular, infraclavicular, and axillary nodes (Figure 31-58). The axillary nodes drain lymph from the chest wall, breasts, arms, and hands. A tumour of one breast sometimes involves nodes on the opposite side, as well as those on the same side.

To palpate the lymph nodes, have the patient sit with her arms at her sides and muscles relaxed. While facing the patient and standing on the side you are examining, support the patient's arm in a flexed position and abduct the arm from the chest wall. Place the free hand against the patient's chest wall and high in the axillary hollow. With the fingertips, press gently down over the surface of the ribs and muscles. Palpate the axillary nodes with the fingertips gently rolling soft tissue (Figure 31-59). Palpate four areas of the axilla: at the edge of the pectoralis major muscle along the anterior axillary line, the chest wall in the midaxillary area, the upper part of the

Figure 31-59 Support the patient's arm, and palpate axillary lymph nodes.

humerus, and the anterior edge of the latissimus dorsi muscle along the posterior axillary line.

Normally lymph nodes are not palpable. Carefully assess each area, and note their number, consistency, mobility, and size. One or two small, soft, nontender palpable nodes are normal. A palpable node feels like a small mass that is hard, tender, and immobile. Also palpate along the upper and lower clavicular ridges. Reverse the procedure for the patient's other side.

It is sometimes difficult for the patient to learn to palpate for lymph nodes. Lying down with the arm abducted makes the area more accessible. Instruct the patient to use her left hand for the right axillary and clavicular areas. Take the patient's fingertips and move them in the proper fashion. Then have the patient use her right hand to palpate for nodes on the left side.

With the patient lying supine and one arm behind the head (alternating with each breast), palpate the patient's breast tissue. The supine position allows the breast tissue to flatten evenly against the chest wall. The patient raises her hand and places it behind the neck to further stretch and position breast

Figure 31-60 A, The patient lies flat with arm abducted and hand under head to help flatten breast tissue evenly over the chest wall. B, Each breast is palpated in a systematic fashion.

tissue evenly (Figure 31-60, A). Place a small pillow or towel under the patient's shoulder blade to further position breast tissue.

The consistency of normal breast tissue varies widely. The breasts of a young patient are firm and elastic. In an older patient, the tissue sometimes feels stringy and nodular. The patient's familiarity with the texture of her own breasts is very important. Patients gain familiarity through BSE (Box 31-24).

If the patient complains of a mass, examine the opposite breast to ensure an objective comparison of normal and abnormal tissue. Use the pads of the first three fingers to compress breast tissue gently against the chest wall, noting tissue consistency (Figure 31-61, B). Perform palpation systematically in one of three ways: (1) clockwise or counterclockwise, forming small circles with the fingers along each quadrant and the tail; (2) using a vertical technique with the fingers moving up and down each quadrant; or (3) palpating from the centre of the breast in a radial fashion, returning to the areola to begin each spoke (see Figure 31-61, C). Whatever approach you use, be sure to cover the entire breast and tail, directing attention to any areas of tenderness.

When palpating large, pendulous breasts, use a bimanual technique. Support the inferior portion of the breast in one hand while using the other hand to palpate breast tissue against the supporting hand.

During palpation, note the consistency of breast tissue. It normally feels dense, firm, and elastic. With menopause, breast tissue shrinks and becomes softer. The lobular feel of glandular tissue is normal. The lower edge of each breast sometimes feels firm and hard. This is the normal inframammary ridge

BOX 31-24 PATIENT TEACHING

Female Breast Assessment

Objectives

- Patient will perform breast self-examination (BSE) (see Box 31-22, p. 604).
- Patient will have screening mammography performed at recommended intervals, beginning at age 50.
- Patient will identify signs and symptoms of breast cancer.
- Patient will identify signs and symptoms of benign (fibrocystic) breast disease.
- Patient will follow a low-fat diet.

Teaching Strategies

- Have patient perform return demonstration of BSE, and offer the opportunity to ask questions.
- Explain recommended frequency of mammography and assessment by a health care provider.
- Discuss signs and symptoms of breast cancer.
- Discuss signs and symptoms of benign (fibrocystic) breast disease.
- Inform a woman who is obese or who has a family history of breast cancer that she is at higher risk for the disease (Canadian Cancer Society, 2012a). Encourage dietary changes, including limiting meat consumption to well-trimmed, lean beef, pork, or lamb; removing skin from cooked chicken before eating it; selecting tuna and salmon packed in water and not oil; and using low-fat dairy products.
- Encourage patient to reduce intake of caffeine and theophyllines. Although this approach is controversial, it will possibly reduce symptoms of benign (fibrocystic) breast disease.

Evaluation

- Have patient demonstrate BSE.
- During follow-up visit, determine whether patient has had mammography performed.
- Ask patient to explain frequency of mammography.
- Have patient describe signs and symptoms of breast cancer compared with benign (fibrocystic) breast disease.

and not a tumour. It helps to move the patient's hand so that she can feel normal tissue variations. Palpate abnormal masses to determine location in relation to quadrants, diameter in centimetres, shape (e.g., round or discoid), consistency (soft, firm, or hard), tenderness, mobility, and discreteness (clear or unclear boundaries).

Cancerous lesions are hard, fixed, nontender, irregular in shape, and usually unilateral. A common benign condition of the breast is **benign (fibrocystic) breast disease**. Bilateral lumpy, painful breasts and sometimes nipple discharge characterize this condition. Symptoms are more apparent during the menstrual period. When palpated, the cysts (lumps) are soft, well differentiated, and movable. Deep cysts feel hard.

Give special attention when palpating the nipple and areola. Palpate the entire surface gently. Use the thumb and index finger to compress the nipple, and note any discharge. During the examination of the nipple and areola, the nipple sometimes becomes erect with wrinkling of the areola. These changes are normal.

After completing the examination, have the patient demonstrate self-palpation. Observe the patient's technique, and emphasize the importance of a consistent and systematic

Figure 31-61 Various methods for palpation of the breast. **A**, Palpate from top to bottom in vertical strips. **B**, Palpate in concentric circles. **C**, Palpate out from the centre in wedge sections. **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 471). St Louis, MO: Mosby.

approach. Urge the patient to see her health care provider if she discovers an abnormal mass during self-examination. She also needs to know all of the signs and symptoms of breast cancer.

Male Breasts

Examination of the male breast is relatively easy. Inspect the nipple and areola for nodules, edema, and ulceration. An enlarged male breast results from obesity or glandular enlargement. Breast enlargement in young males results from steroid use. Fatty tissue feels soft, whereas glandular tissue is firm. Use the same techniques to palpate for masses used in examination of the female breast.

safety alert Men, especially men who have a first-degree relative (e.g., mother, sister) with breast cancer, are at risk for breast cancer and need to palpate their breasts at regular intervals. In discussion with their health care provider, these men may also be scheduled for routine mammograms.

Abdomen

The abdominal examination is complex because of the number of organs located within and near the abdominal cavity. A thorough nursing history (Table 31-27) helps interpret physical signs. The examination includes an assessment of structures of the lower GI tract in addition to the liver, stomach, uterus, ovaries, kidneys, and bladder. Abdominal pain is one of the most common symptoms that patients report when seeking medical care. An accurate assessment requires matching patient history data with a careful assessment of the location of physical symptoms.

Assess the organs anteriorly and posteriorly. A system of landmarks help map out the abdominal region. The xiphoid process (tip of the sternum) is the upper boundary of the anterior abdominal region. The symphysis pubis marks the lower boundary. Divide the abdomen into four imaginary quadrants (Figure 31-62, A), and refer to assessment findings and record them in relation to each quadrant. Posteriorly, the lower ribs and heavy back muscles protect the kidneys, which are located from the T12 to L3 vertebrae (Figure 31-62,

B). The costovertebral angle formed by the last rib and vertebral column is a landmark used during kidney and liver palpation.

During the abdominal examination, the patient needs to relax. A tightening of abdominal muscles hinders palpation. Ask the patient to void before beginning. Be sure the room is warm, and drape upper chest and legs. The patient lies supine or in a dorsal recumbent position with the arms at the sides and knees slightly bent. Place small pillows beneath the knees. If the patient places the arms under the head, the abdominal muscles tighten. Proceed calmly and slowly, being sure that there is adequate lighting. Expose the abdomen from just above the xiphoid process down to the symphysis pubis. Warm hands and stethoscope further promote relaxation. Ask the patient to report pain and point out tender areas. Assess tender areas last.

The order of an abdominal examination differs slightly from previous assessments. Begin with inspection and follow with auscultation. By using auscultation before palpation there is less chance of altering the frequency and character of bowel sounds. Be sure to have a tape measure and marking pen available during the examination.

Inspection

Make it a habit to observe the patient during routine care activities. Note the patient's posture and look for evidence of abdominal splinting: lying with the knees drawn up or moving restlessly in bed. A patient free from abdominal pain will not guard or splint the abdomen. To inspect the abdomen for abnormal movement or shadows, stand on the patient's right side and inspect from above the abdomen. By sitting down to look across the abdomen, assess abdominal contour. Direct the examination light over the abdomen.

Skin. Inspect the skin over the abdomen for colour, scars, venous patterns, lesions, and striae (stretch marks). The skin is subject to the same colour variations as the rest of the body. Venous patterns are normally faint, except in thin patients. Striae result from stretching of tissue by obesity or pregnancy. Artificial openings indicate drainage sites resulting from surgery (see Chapter 48) or an ostomy (see Chapters 43 and 44). Scars reveal evidence of past trauma or surgery that has

► TABLE 31-27 Nursing History for Abdominal Assessment

Assessment Category

If patient has abdominal or low back pain, assess character of pain in detail (location, onset, frequency, precipitating factors, aggravating factors, type of pain, severity, course).

Carefully observe patient's movement and position, including lying still with knees drawn up, moving restlessly to find comfortable position, and lying on one side or sitting with knees drawn to chest.

Assess normal bowel habits and stool character; ask if patient uses laxatives.

Determine if patient has had abdominal surgery, trauma, or diagnostic tests of gastrointestinal (GI) tract.

Assess if patient has had recent weight changes or intolerance to diet (e.g., nausea, vomiting, cramping, especially in last 24 hours).

Assess for difficulty in swallowing, belching, flatulence (gas), bloody emesis (hematemesis), black or tarry stools (melena), heartburn, diarrhea, or constipation.

Ask if patient takes anti-inflammatory medication (e.g., aspirin, ibuprofen, steroids) or antibiotics.

Ask patient to locate tender areas before examination begins.

Inquire about family history of cancer, kidney disease, alcoholism, hypertension, or heart disease.

Determine if female patient is pregnant; note last menstrual period.

Assess patient's usual intake of alcohol.

Review patient's history for the following: health care occupation, hemodialysis, intravenous drug user, household or sexual contact with hepatitis B virus (HBV) carrier, heterosexual person with more than one sex partner in previous 6 months, sexually active homosexual or bisexual male, international traveller in area of high HBV infection rate.

Rationale

Pattern of characteristics of pain helps determine its source.

Positions assumed by patient reveals nature and source of pain, including peritonitis, renal stone, and pancreatitis.

Data compared with physical findings help identify cause and nature of elimination problems.

Surgical or traumatic alterations of abdominal organs cause changes in expected findings (e.g., position of underlying organs). Diagnostic tests change character of stool.

Data possibly indicate alterations in upper GI tract (stomach or gallbladder) or lower colon.

These characteristic signs and symptoms indicate gastrointestinal alterations.

Pharmacological agents cause GI upset or bleeding.

Assess painful areas last to minimize discomfort and anxiety.

Data possibly reveal risk for alterations identifiable during examination.

Pregnancy causes changes in abdominal shape and contour.

Chronic alcohol ingestion causes gastrointestinal and liver problems.

Risk factors for HBV exposure.

Figure 31-62 A, Anterior view of abdomen divided by quadrants. B, Posterior view of abdominal section.

created permanent changes in underlying organ anatomy. Bruising indicates accidental injury, physical abuse, or a type of bleeding disorder. Ask if the patient self-administers injections (e.g., low-molecular-weight heparin or insulin). Unexpected findings include generalized colour changes such as jaundice or cyanosis. A glistening, taut (tight) appearance indicates ascites.

Umbilicus. Note the position; shape; colour; and signs of inflammation, discharge, or protruding masses. A normal umbilicus is flat or concave with the colour the same as that of the surrounding skin. Underlying masses cause displacement of the umbilicus. An everted (pouched-out) umbilicus

usually indicates distension. **Hernias** (protrusion of abdominal organs through the muscle wall) cause upward protrusion of the umbilicus. Normally the umbilical area does not emit discharge.

Contour and Symmetry. Inspect for contour, symmetry, and surface motion of the abdomen, noting any masses, bulging, or distension. A flat abdomen forms a horizontal plane from the xiphoid process to the symphysis pubis. A round abdomen protrudes in a convex sphere from the horizontal plane. A concave abdomen appears to sink into the muscular wall. Each of these findings is normal if the abdomen's shape is symmetrical. In older adults, there is often an

overall increased distribution of adipose tissue. The presence of masses on only one side, or asymmetry, possibly indicates an underlying pathological condition.

Intestinal gas, a tumour, or fluid in the abdominal cavity causes distension. When distension is generalized, the entire abdomen protrudes. The skin often appears taut, as if it were stretched over the abdomen. When gas causes distension, the flanks do not bulge. However, if fluid is the source of the problem, the flanks bulge. Ask the patient to roll onto one side. A protuberance forms on the dependent side if fluid is the cause of the distension. Ask the patient if the abdomen feels unusually tight. Be careful not to confuse distension with obesity. In obesity, the abdomen is large, rolls of adipose tissue are often present along the flanks, and the patient does not complain of tightness in the abdomen. If abdominal distension is expected, measure the abdomen by placing a tape measure around the abdomen at the level of the umbilicus. Consecutive measurements will show any increase or decrease in distension. Use a marking pen to indicate the location of tape measure.

Enlarged Organs or Masses. Observe the contour of the abdomen while asking the patient to take a deep breath and hold it. Normally, the contour remains smooth and symmetrical. This manoeuvre forces the diaphragm downward and reduces the size of the abdominal cavity. Any enlarged organs in the upper abdominal cavity (e.g., liver or spleen) will descend below the rib cage to cause a bulge. Perform a closer examination with palpation.

To evaluate the abdominal musculature, have the patient raise his or her head off the examination table. This position causes superficial abdominal wall masses, hernias, and muscle separations to become more apparent.

Movement or Pulsations. Inspect for movement. Normally, men breathe abdominally and women breathe more costally. A patient with severe pain has diminished respiratory movement and tightens the abdominal muscles to guard against the pain. Closely inspect for peristaltic movement and aortic pulsation by looking across the abdomen from the side. These movements are visible in thin patients; otherwise no movement is present.

Auscultation

Auscultate before palpation during the abdominal assessment because manipulation of the abdomen alters the frequency and intensity of bowel sounds. Ask the patient not to talk. Patients with GI tubes connected to suction need them temporarily turned off before beginning the examination.

Bowel Motility. Peristalsis, or the movement of contents through the intestines, is a normal function of the small and large intestine. Bowel sounds are the audible passage of air and fluid that peristalsis creates. Place the warmed diaphragm of the stethoscope lightly over each of the four quadrants. Normally, air and fluid move through the intestines, creating soft gurgling or clicking sounds that occur irregularly 5 to 35 times per minute (Seidel et al., 2011). Sounds usually last from half a second to several seconds. It normally takes 5 to 20 seconds to hear a bowel sound. However, it takes 5 minutes of continuous listening before determining that bowel sounds are absent (Seidel et al., 2011). Auscultate all four quadrants to be sure that you do not miss any sounds. The best time to auscultate is between meals. Sounds are generally described as normal, audible, absent, hyperactive, or hypoactive. Absent sounds indicate a lack of peristalsis,

* BOX 31-25 PATIENT TEACHING

Abdominal Assessment

Objectives

- Patient will maintain normal bowel elimination.
- Patient will achieve pain relief.
- Patients at high risk for **hepatitis B virus (HBV)** will receive immunization.
- Patient will identify signs and symptoms of colon cancer.

Teaching Strategies

- Explain factors that promote normal bowel elimination, such as diet, regular exercise, limited use of over-the-counter drugs causing constipation, establishment of regular elimination schedule, and a good fluid intake (see Chapter 44). Stress importance for older adults.
- Caution patients about dangers of excessive use of laxatives or enemas.
- Instruct patient to have acute abdominal pain evaluated by a health care provider.
- If patient has chronic pain, explain measures used for pain relief (e.g., relaxation exercises, positioning) (see Chapter 41).
- If patient is a health care worker or has contact with blood or fluids of affected person, encourage patient to receive the series of three HBV vaccine doses.
- Instruct patient about warning signs of colon cancer, including rectal bleeding, cramping pain in lower abdomen, black or tarry stools, blood in stool, and a change in bowel habits (constipation or diarrhea).

Evaluation

- Reassess patient's bowel elimination pattern and stool character after therapies begin.
- Observe patient using pain-relief measures and reassess character of pain.
- During follow-up clinic or office visit, check patient's compliance with HBV vaccine schedule.
- Ask patient to state signs and symptoms of colon cancer.

possibly due to late-stage bowel obstruction, **paralytic ileus**, or **peritonitis**. Normally, absent or hypoactive bowel sounds occur postoperatively following general anesthesia. Hyperactive sounds are loud, "growling" sounds called **borborygmi**, which indicate increased gastrointestinal motility. Inflammation of the bowel, anxiety, diarrhea, bleeding, excessive ingestion of laxatives, and reaction of the intestines to certain foods cause increased motility (Box 31-25).

Vascular Sounds. Bruits indicate narrowing of the major blood vessels and disruption of blood flow. The presence of bruits in the abdominal area will possibly reveal aneurysms or stenotic vessels. Use the bell of the stethoscope to auscultate in the epigastric region and each of the four quadrants. Normally there are no vascular sounds over the aorta (midline through the abdomen) or femoral arteries (lower quadrants). Renal artery bruits are heard by placing the stethoscope over each upper quadrant anteriorly or over the costovertebral angle posteriorly. Report a bruit immediately to a health care provider.

Kidney Tenderness. With the patient sitting or standing erect, use direct or indirect percussion to assess for kidney inflammation. With the ulnar surface of the partially closed fist, percuss posteriorly the costovertebral angle at the scapular

Figure 31-63 Light palpation of abdomen.

Figure 31-64 Deep palpation of abdomen.

line. If the kidneys are inflamed, the patient feels tenderness during percussion.

Palpation

Palpation primarily detects areas of abdominal tenderness, distension, or masses. As skill base increases, learn to palpate for specific organs. Use light and deep palpation.

Use light palpation over each abdominal quadrant. Initially avoid areas previously identified as problem spots. Lay the palm of the hand with fingers extended and approximated lightly on the abdomen. Explain the manoeuvre to the patient, and then with the palmar surface of the fingers depress approximately 1.3 cm in a gentle dipping motion (Figure 31-63). Avoid quick jabs, and use smooth, coordinated movements. For ticklish patients, first place the patient's hand on the abdomen with your hand on the patient's; continue this until the patient tolerates palpation.

Use a systematic palpation approach for each quadrant and assess for muscular resistance, distension, tenderness, and superficial organs or masses. Observe the patient's face for signs of discomfort. The abdomen is normally smooth with consistent softness and nontender without masses. The older adult often lacks abdominal tone. Guarding or muscle tenseness sometimes occurs while palpating a sensitive area. If tightening remains after the patient relaxes, peritonitis, acute **cholecystitis**, or appendicitis is sometimes the cause. It is easy to detect a distended bladder with light palpation. Normally the bladder lies below the umbilicus and above the symphysis pubis. Routinely check for a distended bladder if a patient has been unable to void (e.g., because of anesthesia or sedation) or has been incontinent, or if an indwelling urinary catheter is not draining well.

With practice and experience, perform deep palpation to delineate abdominal organs and to detect less obvious masses. You will need short fingernails. It is important for the patient to be relaxed while the hands depress approximately 2.5 to 7.5 cm into the abdomen (Figure 31-64). Never use deep palpation over a surgical incision or over extremely tender organs. It is also unwise to use palpation on abnormal masses. Deep pressure causes tenderness in the healthy patient over the

cecum, sigmoid colon, aorta, and the midline near the xiphoid process (Seidel et al., 2011).

Survey each quadrant systematically. Palpate masses for size, location, shape, consistency, tenderness, pulsation, and mobility. Test for rebound tenderness by pressing a hand slowly and deeply into the involved area and then letting go quickly. The test is positive if the patient feels pain with the release of the hand. Rebound tenderness occurs in patients with peritoneal irritation such as occurs in appendicitis; **pancreatitis**; or any peritoneal injury causing bile, blood, or enzymes to enter the peritoneal cavity.

Aortic Pulsation. To assess aortic pulsation, palpate with the thumb and forefinger of one hand deeply into the upper abdomen, just left of the midline. Normally a pulsation is transmitted forward. If there is enlargement of the aorta from an **aneurysm** (localized dilation of a vessel wall), the pulsation expands laterally. Do not palpate a pulsating abdominal mass. In obese patients it is often necessary to palpate with both hands, one on each side of the aorta.

safety alert When enlargement from an aneurysm is present, only lightly palpate this area. In addition, only someone with advanced education and experience should perform palpation of this area.

Female Genitalia and Reproductive Tract

Examination of the female genitalia is embarrassing to the patient unless you use a calm, relaxed approach. The gynecological examination is one of the most difficult experiences for adolescents. Cultural background further adds to apprehension. In some cultures, a strong social value may exist where women do not expose their bodies to men or even to other women. In other cultures, the examination of genitalia may be considered offensive. Cultural expression of these values, and the level of emotional or physical comfort with the procedure, needs to be explored prior to any genital exam. The lithotomy position assumed during the examination is an added source of embarrassment. It is often the nurse's role to provide a thorough explanation as to the reason for the examination and

the procedures that will be used. Patient acceptance and comfort can be augmented through correct positioning and draping. Adolescents sometimes choose to have parents present in the examination room.

Sometimes a patient requires a complete examination of the female reproductive organs: assessment of the external genitalia and a vaginal examination. The nurse will examine external genitalia while performing routine hygiene measures or preparing to insert a urinary catheter. An internal examination is part of each woman's preventive health care because ovarian cancer causes more deaths than any other cancer of the female reproductive system (CCS Steering Committee, 2010).

Adolescents and young adults are examined because of the growing incidence of sexually transmitted infections (STIs). The average age of menarche among young girls has declined, and the majority of male and female teenagers are sexually active by age 19 (Hockenberry & Wilson, 2007). It is important to assess the patient's level of anxiety as you obtain the nursing history (Table 31-28). Rectal and anal assessment are combined with this examination because the patient assumes a lithotomy or dorsal recumbent position.

Preparation of the Patient

As a beginning nurse, your responsibility will be assisting the patient's health care provider with the examination. For a complete examination, you will need the following special equipment: examination table with stirrups, vaginal speculum of correct size, adjustable light source, sink, clean disposable gloves, sterile cotton swabs, glass slides, plastic or wooden spatula, cervical brush or broom device, cytologic fixative, and culture plates or media (Seidel et al., 2011).

Make sure the equipment is ready before the examination begins. Ask the patient to empty her bladder so that the uterus and ovaries are readily palpable. Often it is necessary to collect a urine specimen. Assist the patient to the lithotomy position, in bed or on an examination table for the external genitalia assessment. Assist the patient into stirrups for a speculum examination. Have the woman stabilize each foot in a stirrup and then have her slide the buttocks down to the edge of the examining table. Place a hand at the edge of the table and instruct the patient to move until touching the hand. The patient's arms should be at her sides or folded across the chest to prevent tightening of abdominal muscles.

► **TABLE 31-28** Nursing History for Female Genitalia and Reproductive Tract Assessment

Assessment Category

Determine if patient has had previous illness or surgery involving reproductive organs, including sexually transmitted infections (STIs).
Determine if patient has received a human papillomavirus (HPV) vaccine.

Review menstrual history, including age at menarche, frequency and duration of menstrual cycle, character of flow (e.g., amount, presence of clots), presence of dysmenorrhea (painful menstruation), pelvic pain, dates of last two menstrual periods, and premenstrual symptoms.

Ask patient to describe obstetrical history, including each pregnancy and history of abortions or miscarriages.

Ask patient to describe current and past contraceptive practices and problems encountered. Determine whether patient uses safe sex practices. Discuss risk of STIs and HIV infection.

Sexual history reveals risk for and understanding of STIs.

Assess if patient has signs and symptoms of vaginal discharge, painful or swollen perianal tissues, or genital lesions.

Determine if patient has symptoms or history of genitourinary problems, including burning during urination, frequency, urgency, nocturia, hematuria, incontinence, or stress incontinence (see Chapter 43).

Ask if patient has had signs of bleeding outside of normal menstrual period or after menopause or has had unusual vaginal discharge.

Determine if patient has history of HPV (condyloma acuminatum, herpes simplex, or cervical dysplasia); has multiple sex partners; smokes cigarettes; has had multiple pregnancies; or was young at first intercourse.

Determine if patient is older than 40, is obese, and has history of ovarian dysfunction, breast or endometrial cancer, irradiation of pelvic organs, or endometriosis; has family history of ovarian, breast, or colon cancer; has history of infertility or nulliparity; or uses estrogen (alone) hormone replacement therapy.

Determine if patient is postmenopausal, obese, or infertile; had early menarche; had late menopause; has history of hypertension, diabetes, gallbladder disease, or polycystic ovary disease; has family history of endometrial, breast, or colon cancer; or has a history of estrogen-related exposure (estrogen replacement therapy, tamoxifen use).

Rationale

Illness or surgery influences appearance and position of organs being examined.

HPV vaccine is recommended for females (ages 9–26) to prevent cervical cancer (Public Health Agency of Canada, 2006). HPV increases patient's risk for development of cervical cancer. This information helps to reveal level of reproductive health, including normalcy of menstrual cycle.

Observed physical findings will vary, depending on woman's history of pregnancy.

Use of certain types of contraceptives influence reproductive health (e.g., sensitivity reaction to spermicidal jelly).

These signs and symptoms may indicate STI or other pathological condition.

Urinary problems are associated with gynecological disorders, including STIs.

These are warning signs for cervical and endometrial cancer or vaginal infection.

These are risk factors for cervical cancer. Vaccines are available for HPV for females 9–26 years of age.

These are risk factors for ovarian cancer.

These are risk factors for endometrial cancer.

Some women suffering from pain or deformity of the joints are unable to assume a lithotomy position. In this situation, it is necessary to have the patient abduct only one leg or to have another assist in separating the patient's thighs. Also, use the side-lying position with the patient on the left side with the right thigh and knee drawn up to her chest.

Give a square drape or sheet to the patient. She holds one corner over her sternum, the adjacent corners fall over each knee, and the fourth corner covers the perineum. After the examination begins, lift the drape over the perineum. The male examiner always needs to have a female attendant present during the examination. A female examiner may prefer to work alone but should have a female attendant if the patient is particularly anxious or emotionally unstable.

External Genitalia

Make sure the perineal area is well illuminated. Wear clean gloves on both hands to prevent contact with infectious organisms. The perineum is extremely sensitive and tender; do not touch the area suddenly without warning the patient. It is best to touch the neighbouring thigh first before advancing to the perineum.

While sitting at the end of the examination table or bed, inspect the quantity and distribution of hair growth. Preadolescents have no pubic hair. During adolescence, hair grows along the labia, becoming darker, coarser, and curlier. In an adult, hair grows in a triangle over the female perineum and along the medial surfaces of the thighs. Hair is normally free of nits and lice. The underlying skin is free of inflammation, irritation, or lesions.

An increasingly common practice among younger women is the removal of genital hair by means of waxing or shaving. Assess the genital region in these patients with respect to abrasion, ingrown hair, irritation from clothing, and signs of infection. Patients who remove the hair in their genital region should be instructed regarding increased hygiene practices (Herbenick et al., 2010).

Inspect surface characteristics of the labia majora. The skin of the perineum is smooth, clean, and slightly darker than other skin. The mucous membranes appear dark pink and moist. The labia majora are gaping or closed and appear dry or moist. They are usually symmetrical. After childbirth, the labia majora separate, causing the labia minora to become more prominent. When a woman reaches menopause, the labia majora become thinned. With advancing age, they become **atrophied** (reduced in size). The labia majora are normally without inflammation, edema, lesions, or lacerations.

To inspect the remaining external structures, use your non-dominant hand and gently place the thumb and index finger inside the labia minora and retract the tissues outwardly (Figure 31-65). Be sure to have a firm hold to avoid repeated retraction against the sensitive tissues. Use the other hand to palpate the labia minora between the thumb and second finger. On inspection, the labia minora are normally thinner than the labia majora, and one side is sometimes larger. The tissue feels soft on palpation and without tenderness. The size of the clitoris is variable, but it normally does not exceed 2 cm in length and 0.5 cm in width. Look for atrophy, inflammation, or adhesions. If inflamed, the clitoris will be a bright cherry red. In young women, it is a common site for syphilitic lesions, or **chancres**, which appear as small open ulcers that drain serous material. Some older women have malignant changes that result in dry, scaly, nodular lesions.

Figure 31-65 Female external genitalia.

Inspect the urethral orifice carefully for colour and position. It is normally intact without inflammation. The urethral meatus is anterior to the vaginal orifice and is pink. It appears as a small slit or pinhole opening just above the vaginal canal. Note any discharge, polyps, or fistulas.

Inspect the vaginal orifice (introitus), for inflammation, edema, discolouration, discharge, and lesions. Normally, the introitus is a thin, vertical slit or a large orifice. The tissue is moist. While inspecting the vaginal orifice, note the condition of the hymen, which is just inside the introitus. In the virgin, the hymen restricts the opening of the vagina. Only remnants of the hymen remain after sexual intercourse.

Inspect the anus, looking for lesions and hemorrhoids. After completion of the external examination, dispose of examination gloves and offer the patient perineal hygiene.

Patients who are at risk for contracting a sexually transmitted infection (STI) need to learn to perform a genital self-examination (GSE) (Box 31-26). The purpose of the examination is to detect any signs or symptoms of an STI. Many people do not know they have an STI (e.g., chlamydia), and some STIs (e.g., syphilis) remain undetected for years.

Speculum Examination of Internal Genitalia

An examination of the internal genitalia requires much skill and practice. Advanced nurse practitioners and primary care providers will perform this examination. Beginning students will more than likely only observe the procedure or assist the examiner by helping the patient with positioning, handing off specimen supplies, and comforting the patient. A detailed presentation of the internal genital exam can be found in *Physical Examination and Health Assessment*, First Canadian Edition (Jarvis et al., 2009). The examination involves use of a plastic or metal speculum, consisting of two blades and an adjustment device. The examiner inserts the speculum into the vagina to assess the internal genitalia for cancerous lesions and other abnormalities. During the examination, the examiner will collect a specimen for a Papanicolaou (Pap) test for cervical and vaginal cancer.

BOX 31-26 PATIENT TEACHING

Female Genitalia and Reproductive Tract Assessment

Objectives

- Patient will pursue routine gynecological examinations based on her level of risk for cervical cancer and other gynecological pathology.
- Patient with a sexually transmitted infection (STI) will follow safe sex practices.
- Patient will use measures to prevent acquisition and transmission of STIs.

Teaching Strategies

- Instruct patient about purpose and recommended frequency of **Papanicolaou (Pap) smears** and gynecological examinations. Explain that the Pap smear is relatively painless and needed annually with a pelvic examination for women who are sexually active or who are over the age of 21. Patients are screened more often if certain risk factors exist such as a weak immune system, multiple sex partners, smoking, and a history of infections (e.g., human papillomavirus [HPV]).
- Counsel patient with an STI about diagnosis and treatment.
- Instruct in genital self-examination (GSE): Using a mirror, position self in order to examine the area covered by the pubic hair. Spread the hair apart, looking for bumps, sores, or blisters. Also, look for any warts, which appear as small, bumpy spots and that enlarge to fleshy, cauliflower-like lesions. Next, spread the outer vaginal lips apart and look at the clitoris for bumps, blisters, sores, or warts. Also look at both sides of the inner vaginal lips. Inspect the area around the urinary and vaginal opening for bumps, blisters, sores, or warts.
- Explain warning signs of STIs: pain or burning on urination, pain during sex, pain in pelvic area, bleeding between menstruation, itchy rash around vagina, and abnormal vaginal discharge.
- Teach measures to prevent STIs: male partner's use of condoms, restricting number of sexual partners, avoiding sex with individuals who have several other partners, and perineal hygiene measures.
- Tell patients with an STI to inform sexual partners of the need for an examination and treatment.
- Reinforce the importance of performing perineal hygiene (as appropriate).

Evaluation

- Ask patient to explain when she should routinely have a gynecological examination and Pap test.
- Have patient describe ways to prevent transmission of STIs.
- For patient with an STI, determine during follow-up visit if patient has followed safe sexual practices (use nonthreatening inquiry).

Figure 31-66 External and internal male sex organs.

BOX 31-27 PATIENT TEACHING

Male Genitalia Assessment

Objectives

- Patient will describe methods to prevent transmission of sexually transmitted infections (STIs).
- Patient will perform genital self-examination.
- Patient with an STI will follow safe sex practices.

Teaching Strategies

- Counsel patient with an STI about diagnosis and treatment.
- Explain warning signs of STIs: pain on urination and during sex, abnormal penile discharge (different from usual), swollen lymph nodes, or rash or ulcer on skin or genitalia.
- Teach measures to prevent STIs: use of condoms, avoiding sex with infected partner, restricting number of sexual partners, avoiding sex with individuals who have multiple partners, and using regular perineal hygiene.
- Tell patients with an STI to inform their sexual partners of the need to have an examination and treatment.
- Instruct patient to seek treatment as soon as possible if partner becomes infected with an STI.
- Instruct patient in how to perform genital self-examination (see Box 31-28).

Evaluation

- Ask patient to describe methods for preventing and treating STI.
- During a follow-up visit, determine whether patient with an STI has used safe sex practices.

Male Genitalia

An examination of the male genitalia assesses the integrity of the external genitalia, (Figure 31-66) inguinal ring, and canal. Because the incidence of STIs in adolescents and young adults is high, an assessment of the genitalia needs to be a routine part of any health maintenance examination for this age group (Box 31-27). The examination begins by having the patient

void. Make sure the examination room is warm. Have the patient lie supine with the chest, abdomen, and lower legs draped or stand during the examination. Wear clean gloves.

Use a calm, gentle approach to lessen the patient's anxiety. The position and exposure of the body during the examination is embarrassing for some. To minimize the patient's anxiety, it often helps to offer explanations of the steps of examination so the patient anticipates all actions. Manipulate the genitalia gently to avoid causing erection or discomfort. Obtain a thorough history (Table 31-29) before the examination, ensuring that the assessment is complete.

▶TABLE 31-29

Nursing History for Male Genitalia Assessment**Assessment Category**

Review normal urinary elimination pattern, including frequency of voiding; history of nocturia; character and volume of urine; daily fluid intake; symptoms of burning, urgency, and frequency; difficulty starting stream; and hematuria (see Chapter 43).

Assess patient's sexual history and use of safe sex habits (multiple partners, infection in partners, failure to use condom).

Determine if patient has had previous surgery or illness involving urinary or reproductive organs, including STI.

Ask if patient has noted penile pain or swelling, genital lesions, or urethral discharge.

Determine if patient has noticed heaviness or painless enlargement of testis or irregular lumps.

If patient reports an enlargement in inguinal area, assess if it is intermittent or constant, associated with straining or lifting, and painful, and whether pain is affected by coughing, lifting, or straining at stool.

Ask if patient has difficulty achieving erection or ejaculation; also review whether patient is taking diuretics, sedatives, antihypertensives, or tranquilizers.

Rationale

Urinary problems are directly associated with genitourinary problems because of anatomical structure of men's reproductive and urinary systems.

Sexual history reveals risk for and understanding of sexually transmitted infections (STIs) and human immunodeficiency virus (HIV).

Alterations resulting from disease or surgery are sometimes responsible for symptoms or changes in organ structure or function.

These signs and symptoms may indicate STI.

These signs and symptoms are early warning signs for testicular cancer.

Signs and symptoms reflect potential inguinal hernia.

These medications influence sexual performance.

Figure 31-67 Normal male genitalia (circumcised). **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 607). St Louis, MO: Mosby.

adult size and shape and scrotal skin darkens and becomes wrinkled. The penis has no hair, and the scrotum has very little hair (Figure 31-67). Also inspect the skin covering the genitalia for lice, rashes, excoriations, or lesions. Normally the skin is clear, without lesions.

Penis

To inspect penile surfaces thoroughly, manipulate the genitalia or have the patient assist. Inspect the shaft, corona, prepuce (foreskin), glans, and urethral meatus. The dorsal vein is apparent on inspection. In uncircumcised males, retract the foreskin to reveal the glans and urethral meatus. The foreskin usually retracts easily. A small amount of white, thick smegma sometimes collects under this foreskin. Obtain a culture if abnormal discharge is present. The urethral meatus is slitlike and is positioned on the ventral surface just millimetres from the tip of the glans. In some congenital conditions, the meatus is displaced along the penile shaft. The area between the foreskin and glans is a common site for venereal lesions. Gently compress the glans between thumb and index finger; this opens the urethral meatus for inspection of lesions, edema, and inflammation. Normally the opening is glistening and pink without discharge. Palpate any lesion gently to note tenderness, size, consistency, and shape. When inspection and palpation of the glans is complete, pull the foreskin down to its original position.

Continue by inspecting the entire shaft of the penis, including the undersurface, looking for lesions, scars, or edema. Palpate the shaft between the thumb and first two fingers to detect localized areas of hardness or tenderness. A patient who has lain in bed for a prolonged time sometimes develops dependent edema in the penis shaft.

It is important for any male patient to learn to perform a genital self-examination to detect signs or symptoms of STIs. Many people who have an STI do not know it. Self-examination is a routine part of self-care (Box 31-28).

Scrotum

Be particularly cautious while inspecting and palpating the scrotum because the structures lying within the scrotal sac are very sensitive. The scrotum is divided internally into two halves. Each half contains a testicle, epididymis, and the vas

Sexual Maturity

First, note the sexual maturity of the patient by observing the size and shape of the penis and testes; the size, colour, and texture of the scrotal skin; and the character and distribution of pubic hair. Use Tanner stages to assess and document sexual maturation (Jarvis et al., 2009). In stage 1, the penis and scrotum show no change in size and there is no evidence of pubic hair. In stage 2, the testes first increase in size during preadolescence. At this time there is little to no pubic hair. At stage 3, the scrotal hair becomes coarse and dark and the penis begins to enlarge. Further growth and coverage of the pubic area occurs in stage 4 and the glans penis matures and scrotum darkens. By the end of stage 5, the testes and penis enlarge to

► BOX 31-28 Male Genital Self-Examination

All men aged 15 years and older need to perform this examination on a regular basis using the following steps.

Genital Examination

Perform the examination after a warm bath or shower when the scrotal skin is less thick.

Stand naked in front of a mirror, and hold the penis in your hand and examine the head. Pull back the foreskin if uncircumcised to expose the glans.

Inspect and palpate the entire head of the penis in a clockwise motion, looking carefully for any bumps, sores, or blisters (bumps and blisters may be light coloured or red, resemble pimples). Look also for any genital warts (see illustration).

Male genital examination

Look at the opening (urethral meatus) at the end of the penis for discharge.

Look along the entire shaft of the penis for the same signs.

Be sure to separate pubic hair at the base of the penis and carefully examine the skin underneath.

Testicular Self-Examination

Look for swelling or lumps in the skin of the scrotum while looking in the mirror.

Use both hands, placing the index and middle fingers under the testicles and the thumb on top (see illustration).

Testicular self-examination

Gently roll the testicle, feeling for lumps, swelling, soreness, or a change in consistency (hardening).

Find the epididymis (a cordlike structure on the top and back of the testicle; it is not a lump).

Feel for small, pea-sized lumps on the front and side of the testicle. The lumps are usually painless and are abnormal.

Call your health care provider if you are uncertain whether you have detected any abnormal findings.

Photos from Seidel, H. M., Ball, J. W., Dains, J. E., Flynn, J. A., Solomon, B. S., & Stewart, R. W. (2011). *Mosby's guide to physical examination* (7th ed., p. 609). St Louis, MO: Mosby.

deferens, which travels upward into the inguinal ring. Normally the left testicle is lower than the right. Inspect the scrotum's size, shape, and symmetry while observing for lesions or edema. Gently lift the scrotum to view the posterior surface. The scrotal skin is usually loose, and the surface is coarse. The scrotal skin is more deeply pigmented than body skin. Tightening or loss or wrinkling reveal edema. The size of the scrotum normally changes with temperature variations because the dartos muscle contracts in cold and relaxes in warm temperatures. Lumps in the scrotal skin are commonly sebaceous cysts.

Testicular cancer is a solid tumour common in young men ages 18 to 34 years. Early detection is critical. Explain testicular self-examination (see Box 31-28) while examining the patient. The testes are normally sensitive but not tender. The underlying testicles are normally ovoid and approximately 2 to 4 cm in size. Gently palpate the testicles and epididymis between the thumb and first two fingers. The testes feel smooth, rubbery, and free of nodules. The epididymis is resilient. Note the size, shape, and consistency of the organs. The most common symptoms of testicular cancer are a painless enlargement of one testis and the appearance of a palpable, small, hard lump,

about the size of a pea, on the front or side of the testicle. In the older adult, the testicles decrease in size and are less firm during palpation. Continue to palpate the vas deferens separately as it forms the spermatic cord toward the inguinal ring, noting nodules or swelling. It normally feels smooth and discrete.

Inguinal Ring and Canal

The external inguinal ring provides the opening for the spermatic cord to pass into the inguinal canal. The canal forms a passage through the abdominal wall, a potential site for hernia formation. A hernia is a protrusion of a portion of intestine through the inguinal wall or canal. Sometimes an intestinal loop enters the scrotum. Have the patient stand during this portion of the examination.

During inspection, ask the patient to strain or bear down. The manoeuvre will help to make a hernia more visible. Look for obvious bulging in the inguinal area.

Complete the examination by palpating for inguinal lymph nodes. Normally, small, nontender, mobile horizontal nodes are palpable. Any abnormality indicates local or systemic infection or malignant disease.

Rectum and Anus

The rectal examination is usually performed after the genital examination. It is not commonly performed during the examination in young children or adolescents. The examination detects colorectal cancer in its early stages. In men, the rectal examination also detects prostatic tumours. Collect a thorough history (Table 31-30) to detect the patient's risk for bowel or rectal disease or prostatic disease. An examination of the rectum and anus requires much skill and practice. Advanced nurse practitioners and primary care providers will perform

► TABLE 31-30

Nursing History for Rectal and Anal Assessment

Assessment Category	Rationale
Determine whether patient has experienced bleeding from rectum, black or tarry stools (melena), rectal pain, or change in bowel habits (constipation or diarrhea).	These are warning signs of colorectal cancer* or other gastrointestinal alterations.
Determine whether patient has personal or strong family history of colorectal cancer, polyps, or chronic inflammatory bowel disease. Ask if patient is over age 40.	These are risk factors for colorectal cancer.*
Assess dietary habits, including high fat intake, diet high in processed or red meats, or deficient fibre content (inadequate fruits and vegetables).	Bowel cancer is often linked to dietary intake of fat or insufficient fibre intake.*
Determine if patient is obese, is physically inactive, smokes, or consumes alcohol.	Risk factors for colorectal cancer.
Determine whether patient has undergone screening for colorectal cancer (digital examination, fecal occult blood test, flexible sigmoidoscopy, and colonoscopy).	Undergoing this screening reflects understanding and compliance with preventive health care measures.
Assess medication history for use of laxatives or cathartic medications.	Repeated use causes diarrhea and eventual loss of intestinal muscle tone.
Assess for use of codeine or iron preparations.	Codeine causes constipation. Iron turns the color of feces black and tarry.
Ask male patient if he has experienced weak or interrupted urine flow, inability to urinate, difficulty in starting or stopping urine flow, polyuria, nocturia, hematuria, or dysuria. Does patient have continuing pain in lower back, pelvis, or upper thighs?	These are warning signs of prostatic cancer.* Symptoms also suggest infection or prostate enlargement.

*Data from Canadian Cancer Society. (2012). *What is colorectal cancer*. Toronto: Author. Retrieved from <http://www.cancer.ca/Canada-wide/About%20cancer/Types%20of%20cancer/What%20is%20colorectal%20cancer.aspx>.

this examination. Beginning students will more than likely only observe the procedure or assist the examiner by helping the patient with positioning, handing off specimen supplies, and comforting the patient. A detailed presentation of the rectum and anus exam can be found in *Physical Examination and Health Assessment*, First Canadian Edition (Jarvis et al., 2009).

The rectal examination is uncomfortable, so explaining all steps helps the patient relax. Use a calm, slow-paced, gentle approach during the examination. Female patients remain in the dorsal recumbent position following genitalia examination or they assume a side-lying (Sims') position. The best way to examine men is to have the patient stand and bend over forward with hips flexed and upper body resting across the examination table. Examine a nonambulatory patient in Sims' position. Use disposable gloves.

Inspection

Using the nondominant hand, gently retract the buttocks to view the perianal and sacrococcygeal areas. Perianal skin is smooth and more pigmented and coarser than skin over the buttocks. Inspect anal tissue for skin characteristics, lesions, external **hemorrhoids** (dilated veins that appear as reddened protrusions), ulcers, fissures and fistulas, inflammation, rashes, or excoriation. Anal tissues are moist and hairless and the voluntary external muscle sphincter holds the anus closed. Next, ask the patient to bear down as though having a bowel movement. Any internal hemorrhoids or fissures will appear at this time. Use clock reference (e.g., 3 o'clock, 8 o'clock) to describe location of findings. Normally there is no protrusion of tissue.

Digital Palpation

Examine the anal canal and sphincters with digital palpation, and in male patients, palpate the prostate gland to rule out enlargement (Box 31-29). Usually advanced practitioners perform this portion of the examination. This technique will not be discussed here.

Musculoskeletal System

The musculoskeletal assessment can be conducted as a separate examination or integrated into other portions of the total physical examination. Assessment can be performed during other nursing care measures such as bathing or positioning. The assessment of musculoskeletal function focuses on determining range of joint motion, muscle strength and tone, and joint and muscle condition. The assessment of musculoskeletal integrity is especially important when the patient reports pain or loss of function in a joint or muscle. Frequently, muscular disorders are the result of neurological disease. For this reason, health care providers often conduct a neurological assessment simultaneously.

While examining the patient's musculoskeletal function, visualize the anatomy of bone and muscle placement and joint structure (see Chapter 45). Joints vary in their degree of mobility. The spinal vertebrae are examples of slightly movable joints in comparison to the hinge joint movement of the knee or elbow.

For a complete examination, expose the muscles and joints so they are able to move without restriction from clothing and so that they are easy to visualize. Have the patient assume a sitting, supine, prone, or standing position while assessing

BOX 31-29 PATIENT TEACHING

Rectal and Anal Assessment

Objectives

- Patient will have a regular digital examination performed appropriate to age.
- Patient will be able to identify symptoms of colorectal and prostatic cancer.
- Patient will follow a nutritiously sound diet.

Teaching Strategies

- Discuss the Canadian Cancer Society's guidelines presented in the Canadian Cancer Encyclopedia (2011) (see <http://info.cancer.ca/ccce-eccl/default.aspx?cceid=627&Lang=E&toc=13>) for early detection of colorectal cancer with one of the following examination schedules beginning at age 50:
 - Digital rectal examination yearly
 - Fecal occult blood test (FOBT) yearly
 - Flexible sigmoidoscopy (FSIG): visual inspection of the rectum and lower colon with a hollow, lighted tube, performed by a physician every five years
 - Annual FOBT and FSIG every five years (preferred)
- Double-contrast barium enema every five years
- Colonoscopy every 10 years
- Individuals at increased risk should discuss options with their health care provider
- Discuss warning signs of colorectal cancer (see Table 31-30).
- Discuss dietary planning and healthy lifestyle choices to maintain or improve colon health.
- Warn patient against problems caused by overuse of laxatives, cathartic medications, codeine, or enemas.
- Discuss with male patient the Canadian Cancer Society's guidelines presented in the Canadian Cancer Encyclopedia (2011) for early detection of prostatic cancer (<http://info.cancer.ca/ccce-eccl/default.aspx?cceid=1173&toc=41&Lang=E>):
 - Digital rectal examination performed annually after age 50
 - Annual prostate-specific antigen (PSA) blood test for men age 50 and over
 - Prostate ultrasound testing if results of either digital rectal examination or PSA test are suspicious
- Men with a first-degree relative diagnosed with prostate cancer need to begin testing at age 45.
- Discuss the warning signs of prostatic cancer.

Evaluation

- During follow-up visits, determine whether patient has had a rectal examination performed.
- Have patient explain warning signs of colorectal and prostatic cancer.
- Ask patient to describe appropriate lifestyle and food choices for healthy colon.

swinging freely at the sides and the head leading the body. Older adults often walk with smaller steps and a wider base of support. Note foot dragging, limping, shuffling, and the position of the trunk in relation to the legs.

Observe the patient from the side in a standing position. The normal standing posture is upright with parallel alignment of the hips and shoulders (Figure 31-68). There is an even contour of the shoulders, level scapulae and iliac crests, alignment of the head over the gluteal folds, and symmetry of extremities. Looking sideways at the patient, note the normal cervical, thoracic, and lumbar curves. Holding the head erect is normal. As the patient sits, some degree of rounding of the shoulders is normal. Older adults tend to assume a stooped, forward-bent posture with the hips and knees somewhat flexed and arms bent at the elbows, raising the level of the arms.

Common postural abnormalities include lordosis, kyphosis, and scoliosis (Figure 31-69). **Kyphosis**, or hunchback, is an exaggeration of the posterior curvature of the thoracic spine. This postural abnormality is common in the older adult. **Lordosis**, or swayback, is an increased lumbar curvature. A lateral spinal curvature is called **scoliosis**. Loss of height is frequently the first clinical sign of osteoporosis, in which height loss occurs in the trunk as a result of vertebral fracture and collapse. **Osteoporosis** is a metabolic bone disease that causes a decrease in quality and quantity of bone. This disease affects 2 million Canadians, one in every four women and one in every eight men (Osteoporosis Canada, 2010). Osteoporosis affects not only adults; it strikes any age group, including children. Although a small amount of height loss is to be expected with aging, if the amount of loss is great, osteoporosis is likely (Box 31-30). As men and women age, they are more likely to have osteoporotic fractures of the forearm or wrists, hips, and vertebrae (Osteoporosis Canada, 2010).

During general inspection, look at the extremities for overall size, gross deformity, bony enlargement, alignment, and symmetry. Normally, there is bilateral symmetry in length, circumference, alignment, and position and in the number of skin folds (Seidel et al., 2011). A general review pinpoints areas requiring specialized assessment.

Palpation

Apply gentle palpation to all bones, joints, and surrounding muscles during a complete examination. In the case of a focused assessment, examine the involved area and adjacent muscle groups or joints. Note any heat, tenderness, edema, or resistance to pressure. The patient should not feel any discomfort when you palpate. Muscles should be firm.

Range of Joint Motion

The examination includes comparison of both active and passive range of motion (ROM). Ask the patient to put each major joint through active and passive full ROM (see Chapter 45). Learn the correct terminology for the movements that the joints are capable of making (Table 31-32), and instruct the patient in how to move through each range of motion. Demonstrate range of motion to the patient when possible. To assess ROM passively, ask the patient to relax and then passively move the extremities through their range of motion. Compare the same body parts for bilateral equality and symmetry in movement. Figure 31-70 shows an example of range-of-motion positions for the hand and wrist. Do not force a joint into a painful position. Know the normal range of each joint

certain muscle groups. Table 31-31 lists the information gathered in the nursing history.

General Inspection

Observe the patient's gait when he or she enters the examination room. When a patient is unaware of the nature of the observation, gait is more natural. Later, a more formal test has the patient walk in a straight line away and then return to point of origin. Note how the patient walks, sits, and rises from a sitting position. Normally, patients walk with the arms

► **TABLE 31-31** Nursing History for Musculoskeletal Assessment**Assessment Category**

Determine if patient is involved in competitive sports (particularly involving collision and contact), fails to warm up adequately, is in poor physical condition, or had had a rapid growth spurt (adolescents).

Review patient history for use of alcohol and/or caffeine; cigarette smoking; constant dieting; calcium intake less than 500 mg daily; thin and light body frame; nulliparous status; menopause before age 45; estrogen deficiency; postmenopause status; family history of osteoporosis; advanced age; history of fractures/falls; sedentary lifestyle; chronic diseases (Cushing's hyperthyroidism and hypothyroidism, malabsorption/malnutrition disorders, neoplasm); long-term use of corticosteroids, methotrexate, phenytoin, aluminum-containing antacids; lack of weight-bearing exercise; lack of exposure to sunlight or inadequate vitamin D intake (Holcomb, 2005).

Ask patient to describe history of problems in bone, muscle, or joint function (e.g., recent fall, trauma, lifting of heavy objects, history of bone or joint disease with sudden or gradual onset, location of alteration).

Assess nature and extent of pain, including location, duration, severity, predisposing and aggravating factors, relieving factors, and type.

Assess patient's normal activity pattern, including type of exercise routinely performed.

Determine how alteration influences ability to perform activities of daily living (e.g., bathing, feeding, dressing, toileting, ambulating) and social functions (e.g., household chores, work, recreation, sexual activities).

Assess height loss of women over age 50 by subtracting current height from recall of maximum adult height.

Rationale

These are risk factors for sports injury.

These are risk factors for osteoporosis.

History assists in assessing nature of musculoskeletal problem.

Pain frequently accompanies alterations in bone, joints, or muscle. This has implications for not only comfort, but also ability to perform activities of daily living.

Provides baseline in assessment. Sedentary lifestyle and lack of appropriate exercise increases bone loss and risk of fractures.

The extent to which patient is able to perform self-care will determine the level of nursing care. Type and degree of restriction in continuing social activities influence topics for patient education and ability of nurse to identify alternative ways to maintain function.

Measurement is useful screening tool to predict osteoporosis.

Figure 31-68 Inspection of overall body posture. **A**, Anterior view. **B**, Posterior view. **C**, Lateral view. **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 661). St Louis, MO: Mosby.

BOX 31-30 PATIENT TEACHING

Musculoskeletal Assessment

Objectives

- Patient will follow measures to prevent or minimize osteoporosis.
- Patient will assume proper body posture.
- Patient will be able to perform self-care measures.

Teaching Strategies

- Instruct patient in correct postural alignment. Consult with physical therapist to provide patient with exercises for improving posture.
- Recommend women and men age 50 and older for routine screening for osteoporosis (Papaioannou et al., 2010).
- To reduce bone demineralization, instruct older adults in a proper exercise program (e.g., weight-bearing, muscle-strengthening, and balance-training exercise) to be followed three or more times a week.
- Encourage intake of calcium to meet the recommended daily allowance. Increased vitamin D will aid calcium absorption.
- Recommendation for daily calcium intake for children 4 to 8 years (800mg), 9 to 18 years (1300 mg), adults 19 to 50 years (1000 mg), and older adults 50+ years (1200 mg) (Osteoporosis Canada, 2010). If supplementing to achieve recommended calcium intake, instruct patient to take no more than 600 mg of calcium at one time.
- Recommended vitamin D supplementation is 400 to 1000 IU for low-risk adults and 800 to 1200 IU for high-risk older adults (Hanley et al., 2010).
- Explain to patients with low back pain that they will benefit from modification of worker risk factors (e.g., lifting heavy weights, use of protective equipment), regular aerobic exercise, exercises that strengthen the back and increase trunk flexibility, and learning how to lift properly.
- Instruct older adults and those with osteoporosis in proper body mechanics and range-of-motion and moderate weight-bearing exercises (e.g., swimming and walking) to minimize trauma and subsequent fracture of bones.
- Instruct patient in use of assistive devices (e.g., zippers on clothing instead of buttons; elevation of chairs to minimize bending of knees and hips) when patient is unable to perform activities of daily living.
- Instruct older patients to pace activities to compensate for loss in muscle strength and to avoid falls.

Evaluation

- Observe patient's posture.
- Ask patient to describe therapies for preventing osteoporosis.
- Observe patient perform range-of-motion exercises.
- Have patient keep log of regular weight-training exercises.
- Ask patient or family members to describe patient's use of self-care aids.

Lordosis Kyphosis Scoliosis
A B C

Figure 31-69 Common postural abnormalities. A, Lordosis. B, Kyphosis. C, Scoliosis.

TABLE 31-32

Terminology for Normal Range-of-Motion Positions

Term	Range of Motion	Examples of Joints
Flexion	Movement decreasing angle between two adjoining bones; bending of limb	Elbow, fingers, knee
Extension	Movement increasing angle between two adjoining bones	Elbow, knee, fingers
Hyperextension	Movement of body part beyond its normal resting extended position	Head
Pronation	Movement of body part so that front or ventral surface faces downward	Hand, forearm
Supination	Movement of body part so that the front or ventral surface faces upward	Hand, forearm
Abduction	Movement of extremity away from midline of body	Leg, arm, fingers
Adduction	Movement of extremity toward midline of body	Leg, arm, fingers
Internal rotation	Rotation of joint inward	Knee, hip
External rotation	Rotation of joint outward	Knee, hip
Eversion	Turning of body part away from midline	Foot
Inversion	Turning of body part toward midline	Foot
Dorsiflexion	Flexion of toes and foot upward	Foot
Plantar flexion	Bending of toes and foot downward	Foot

and the extent to which you can move the patient's joints. Range of motion is equal between contralateral joints. Ideally, assess the patient's normal range to determine a baseline for assessing later change.

A **goniometer**, frequently used by physical and occupational therapists, measures the precise degree of motion in a particular joint and is mainly for patients who have a suspected reduction in joint movement. The instrument has two

flexible arms with a 180-degree protractor in the centre. Position the centre of the protractor at the centre of the joint you are measuring (Figure 31-71). The arms extend along the body parts on each side of the protractor. You take a measurement of the joint angle before moving the joint. After taking the joint

Figure 31-70 Range of motion of the hand and wrist. **A**, Metacarpophalangeal flexion and hyperextension. **B**, Finger flexion: thumb to each fingertip and to the base of the little finger. **C**, Finger flexion, fist formation. **D**, Finger abduction. **E**, Wrist flexion and hyperextension. **F**, Wrist radial and ulnar movement. **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 665). St Louis, MO: Mosby.

through a full ROM, measure the angle again to determine the degree of movement. Compare the reading with the normal degree of joint movement.

Joints are typically free from stiffness, instability, swelling, or inflammation. There should be no discomfort when applying pressure to bones and joints. In older adults, joints often become swollen and stiff with reduced ROM resulting from cartilage erosion and fibrosis of synovial membranes (see Chapter 45). If a joint appears swollen and inflamed, palpate it for warmth.

Muscle Tone and Strength

Assess muscle strength and tone during ROM measurement. Integrate these findings with those from the neurological assessment. Note muscle tone, the slight muscular resistance felt as you move the relaxed extremity passively through its ROM.

Ask the patient to allow an extremity to relax or hang limp. This is often difficult, particularly if the patient feels pain in the extremity. Support the extremity, and grasp each limb, moving it through the normal ROM (Figure 31-72). Normal tone causes a mild, even resistance to movement through the entire range.

If a muscle has increased tone, or **hypertonicity**, you will meet considerable resistance with any sudden passive movement of a joint. Continued movement eventually causes the muscle to relax. A muscle that has little tone (**hypotonicity**) feels flabby. The involved extremity hangs loosely in a position determined by gravity.

For assessment of muscle strength, the patient assumes a stable position. The patient performs manoeuvres demonstrating strength of major muscle groups (Table 31-33). Compare symmetrical muscle pairs for strength based on a grading scale of 0 to 5 (Table 31-34). The arm on the dominant side is

normally stronger than the arm on the nondominant side. In the older adult, a loss of muscle mass causes bilateral weakness, but muscle strength remains greater in the dominant arm or leg.

Examine each muscle group. Ask the patient to first flex the muscle you are examining and then to resist when you apply

Figure 31-71 The patient flexes the arm; the goniometer measures joint range of motion. **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 662). St Louis, MO: Mosby.

Figure 31-72 Assessing muscle tone.

an opposing force against that flexion. It is important to not allow the patient to move the joint. Gradually increase pressure to a muscle group (e.g., elbow extension). Have the patient resist the pressure applied by attempting to move against resistance (e.g., elbow flexion). The patient resists until instructed to stop. Vary the amount of pressure applied, then observe the joint move. If you identify a weakness, compare the size of the muscle with its opposite counterpart by measuring the circumference of the muscle body with a tape measure. A muscle that has atrophied feels soft and boggy when palpated.

Neurological System

The neurological system is responsible for many functions, including initiation and coordination of movement, reception and perception of sensory stimuli, organization of thought processes, control of speech, and storage of memory. A close integration exists between the neurological system and all other body systems. For example, urine production relies in part on the adequacy of blood flow to the kidneys, and the size of arterioles supplying the kidneys is under neural control.

TABLE 31-33

Manoeuvres to Assess Muscle Strength

Muscle Group	Manoeuvre
Neck (sternocleidomastoid)	Place hand firmly against patient's upper jaw. Ask patient to turn head laterally against resistance.
Shoulder (trapezius)	Place hand over midline of patient's shoulder, exerting firm pressure. Have patient raise shoulders against resistance.
Elbow	
Biceps	Pull down on forearm as patient attempts to flex arm.
Triceps	As you flex patient's arm, apply pressure against forearm. Ask patient to straighten arm.
Hip	
Quadriceps	When patient is sitting, apply downward pressure to thigh. Ask patient to raise leg up from table.
Gastrocnemius	Patient sits, while examiner holds shin of flexed leg. Ask patient to straighten leg against resistance.

TABLE 31-34 Muscle Strength

Muscle Function Level	SCALES		
	Grade	% Normal	Lovett Scale
No evidence of contractility	0	0	0 (zero)
Slight contractility, no movement	1	10	T (trace)
Full range of motion, gravity eliminated*	2	25	P (poor)
Full range of motion with gravity	3	50	F (fair)
Full range of motion against gravity, some resistance	4	75	G (good)
Full range of motion against gravity, full resistance	5	100	N (normal)

From Barkauskas, V. H., et al. (2002). *Health and physical assessment* (3rd ed.). St Louis, MO: Mosby.

*Passive movement.

An assessment of neurological function alone is quite time consuming. For efficiency, integrate neurological measurements with other parts of the physical examination. For example, test cranial nerve function during the survey of the head and neck. Observe mental and emotional status during the initial interview.

Consider many variables when deciding the extent of the examination. A patient's level of consciousness influences the ability to follow directions. General physical status influences tolerance to assessment. The patient's chief complaint also helps determine the need for a thorough neurological assessment. If the patient complains of headache or a recent loss of function in an extremity, the patient will need a complete neurological review. Table 31-35 reviews the data collected in the nursing history. For a complete examination, you will need the following special equipment:

- Reading material
- Vials containing aromatic substances (e.g., vanilla extract and coffee)
- Opposite tip of cotton swab or tongue blade broken in half
- Snellen eye chart
- Penlight
- Vials containing sugar or salt
- Tongue blade
- Two test tubes, one filled with hot water and the other with cold water
- Cotton balls or cotton-tipped applicators
- Tuning fork
- Reflex hammer

Mental and Emotional Status

You learn a great deal about mental capacities and emotional state by simply interacting with the patient. Ask questions during an examination to gather data and observe the appropriateness of emotions and thoughts. There are special screening tools designed to assess a patient's mental status. A widely used tool in the screening for cognitive impairment is the Montreal Cognitive Assessment, which is focused on the assessment of mild cognitive impairment (Nasreddine et al., 2005); available at <http://www.mocatest.org/>. The Mini-Mental State Examination (MMSE) is another screening instrument developed by Folstein et al. (1975) that measures orientation and cognitive function. The sample questions in Box 31-31 offer examples of questions found on the MMSE. A maximum score on the MMSE is 30. Patients with scores of 21 or less generally reveal cognitive impairment requiring further evaluation.

To ensure an objective assessment, consider the patient's cultural and educational background, values, beliefs, and previous experiences. Such factors influence responses to questions. An alteration in mental or emotional status reflects a disturbance in cerebral functioning. The cerebral cortex controls and integrates intellectual and emotional functioning. Primary brain disorders, medication, and metabolic changes are examples of factors that change cerebral function.

Delirium is a common mental disorder among older adults. It is an acute mental disorder characterized by confusion, disorientation, and restlessness. The acute condition is often misdiagnosed as a form of dementia, a more progressive, organic mental disorder such as Alzheimer's disease. Thus many health care providers miss the underlying cause of the condition. When it occurs, many think it is common older adult behaviour. Delirium is often overlooked in older adults because of a failure to adequately assess mental status. Fortunately, the

► TABLE 31-35

Nursing History for Neurological Assessment

Assessment Category

Rationale

Determine patient use of analgesics, alcohol, sedatives, hypnotics, antipsychotics, antidepressants, nervous system stimulants, or recreational drugs.	These medications alter level of consciousness or cause behavioural changes. Abuse sometimes causes tremors, ataxia, and changes in peripheral nerve function.
Determine if patient has recent history of seizures/convulsions: clarify sequence of events (aura, fall to ground, motor activity, loss of consciousness); character of any symptoms; and relationship of seizure to time of day, fatigue, or emotional stress.	Seizure activity often originates from central nervous system alteration. Characteristics of seizure help determine its origin.
Screen patient for symptoms of headache, tremors, dizziness, vertigo, numbness or tingling of body part, visual changes, weakness, pain, or changes in speech. Presence of any symptom requires more detailed review (onset, severity, precipitating factors or sequence of events).	These symptoms frequently originate from alterations in central nervous system or peripheral nervous system function. Identification of specific patterns aids in diagnosis of pathological condition.
Discuss with patient's family any recent changes in patient's behaviour (e.g., increased irritability, mood swings, memory loss, change in energy level).	Behavioural changes sometimes result from intracranial pathological states.
Assess patient for history of change in vision, hearing, smell, taste, or touch.	Major sensory nerves originate from brain stem. These symptoms help to localize nature of problem.
If an older patient displays sudden acute confusion (delirium), review history for drug toxicity (anticholinergics, diuretics, digoxin, cimetidine, sedatives, antihypertensives, antiarrhythmics), serious infections, metabolic disturbances, heart failure, and severe anemia.	This is one of the most common mental disorders in older people. Condition is always potentially reversible (see Box 31-32).
Review past history for head or spinal cord injury, meningitis, congenital anomalies, neurological disease, or psychiatric counselling.	Factors cause neurological symptoms or behavioural changes to develop, focusing assessment on possible cause.

condition often reverses when it is correctly assessed and the underlying cause is treated (central nervous system [CNS], metabolic, and cardiopulmonary disorders; systemic illnesses; and sensory deprivation or overload) (Stuart & Laraia, 2005). Frequently, patients who develop delirium are labelled with sundown syndrome because the delirium frequently worsens

► BOX 31-31 MMSE Sample Questions

- Orientation to time
"What is the date?"
- Registration
"Listen carefully. I am going to say three words. You say them back after I stop. Ready? Here they are ...
"HOUSE (pause), CAR (pause), LAKE (pause). Now repeat those words back to me."
[Repeat up to five times, but score only the first trial.]
- Naming
"What is this?" [Point to a pencil or pen.]
- Reading
"Please read this and do what it says." [Show examinee the words on the stimulus form.]

► BOX 31-32 Clinical Criteria for Delirium

- **Definition:** An acute disturbance of consciousness that is accompanied by a change in cognition. It is not due to a preexisting or evolving dementia. Delirium develops over a short period of time, usually hours to days, and tends to fluctuate during the course of the day. It is usually a direct physiological consequence of a general medical condition. It is most common in older adults, but occurs occasionally in younger patients.
- There is reduced clarity of awareness of the environment.
- Ability to focus, sustain, or shift attention is impaired (questions must be repeated).
- Irrelevant stimuli easily distract the person.
- There is an accompanying change in cognition (memory impairment, disorientation, or language disturbance).
- Commonly affects recent memory.
- Disorientation usually occurs, with patient disoriented to time, place, or person.
- Language disturbance involves impaired ability to name objects or ability to write; speech is sometimes rambling.
- Perceptual disturbances include misinterpretations, delusions, or visual and auditory hallucinations. Neurological signs include tremor, unsteady gait, asterixis, or myoclonus.

	Abnormal flexion	3
	Abnormal extension	2
	Flaccid	1
TOTAL SCORE		15

and cooperation to unresponsiveness to any form of external stimuli. Talk with the patient, asking questions about events involving the patient or concerns about any health problems. A fully conscious patient responds to questions quickly and expresses ideas logically. With a lowering of the patient's consciousness, use the Glasgow Coma Scale (GCS) for an objective measurement of consciousness on a numerical scale (Table 31-36). The patient needs to be as alert as possible before testing. Use caution when using the scale if a patient has sensory losses (e.g., vision, hearing). The GCS allows evaluation of a patient's neurological status over time. The higher the score, the better the patient's neurological function. Ask short, simple questions such as "What is your name?" "Where are you?" and "What day is this?" Also ask the patient to follow simple commands, such as "Move your toes."

If a patient is not conscious enough to follow commands, try to elicit the pain response. Apply firm pressure with the thumb over the root of the patient's fingernail. The normal response to the painful stimuli is withdrawal of the body part from the stimulus. A patient with serious neurological impairment exhibits abnormal posturing in response to pain. A flaccid response indicates the absence of muscle tone in the extremities and severe injury to brain tissue.

Behaviour and Appearance. Behaviour, moods, hygiene, grooming, and choice of dress reveal pertinent information about mental status. Remain perceptive of the patient's mannerisms and actions during the entire physical assessment. Note nonverbal and verbal behaviours. Does the patient respond appropriately to directions? Does the patient's mood vary with no apparent cause? Does the patient show concern about appearance? Is the patient's hair clean and neatly groomed, and are the nails trim and clean? The patient should behave in a manner expressing concern and interest in the examination. The patient should make eye contact with the nurse and express appropriate feelings that correspond to the situation. Normally, the patient will show some degree of personal hygiene.

Choice and fit of clothing reflect socioeconomic background or personal taste rather than deficiency in self-concept or self-care. Avoid being judgemental, and focus assessment on the appropriateness of clothing for the weather. Older adults

at night. Many practitioners mistake this as being common with old age. Be aware that delirium has occurred in children having surgery (20%) and hospitalized children (8%) (Stuart & Laraia, 2005). Obtain a good history of the patient's behaviour before delirium develops so as to recognize the condition early. Family members are usually a good resource. Box 31-32 summarizes clinical criteria for delirium.

Level of Consciousness. A person's level of consciousness exists along a continuum from full awakening, alertness,

sometimes neglect their appearance because of a lack of energy, finances, or reduced vision.

Language. Normal cerebral function allows a person to understand spoken or written words and to express the self through written words or gestures. Assess the patient's voice inflection, tone, and manner of speech. Normally, the patient's voice has inflections, is clear and strong, and increases in volume appropriately. Speech is fluent. When communication is clearly ineffective (e.g., omission or addition of letters and words, misuse of words, or hesitations), assess for **aphasia**. Injury to the cerebral cortex results in aphasia.

The two types of aphasia are sensory (or receptive) and motor (or expressive). With receptive aphasia, a person cannot understand written or verbal speech. With expressive aphasia, a person understands written and verbal speech but cannot write or speak appropriately when attempting to communicate. A patient sometimes suffers a combination of receptive and expressive aphasia. Assess language capabilities when it is clear that ineffective communication with the patient exists. Some simple assessment techniques are the following:

- Point to a familiar object, and ask the patient to name it.
- Ask the patient to respond to simple verbal and written commands, such as "Stand up" or "Sit down."
- Ask the patient to read simple sentences out loud.

Normally, a patient names objects correctly, follows commands, and reads sentences correctly.

Intellectual Function

Intellectual function includes memory (recent, immediate, and past), knowledge, abstract thinking, association, and judgement. Testing each aspect of function involves a specific technique. However, because cultural and educational background influences the ability to respond to test questions, do not ask questions related to concepts or ideas with which the patient is unfamiliar.

Memory. Assess immediate recall and recent and remote memory. Patients demonstrate immediate recall by repeating a series of numbers (e.g., 7, 4, 1) in the order they are presented or in reverse order. Patients normally recall a series of five to eight digits forward and four to six digits backward.

First ask to test the patient's memory. Then state clearly and slowly the name of three unrelated objects. After mentioning all three, ask the patient to repeat each. Continue until the patient is successful. Then, later in the assessment, ask the patient to repeat the three words again. The patient should be able to identify the three words. Another test for recent memory involves asking the patient to recall events occurring during the same day (e.g., what was eaten for breakfast). Validate information with a family member.

To assess past memory, ask the patient to recall the maiden name of the patient's mother, a birthday, or a special date in history. It is best to ask open-ended questions rather than simple yes/no questions. A patient usually has immediate recall of such information. With older adults, do not interpret a hearing loss as confusion. Good communication techniques are essential throughout the examination to ensure that the patient clearly understands all directions and testing.

Knowledge. Assess knowledge by asking how much the patient knows about his or her illness or the reason for seeking health care. By assessing a patient's knowledge, you can determine a patient's ability to learn or understand. If there is an opportunity to teach, test the patient's mental status by asking for feedback during a follow-up visit.

Abstract Thinking. Interpreting abstract ideas or concepts reflects the capacity for abstract thinking. For an individual to explain common phrases such as "A stitch in time saves nine" or "Don't count your chickens before they're hatched" requires a higher level of intellectual function. Note whether the patient's explanations are relevant and concrete. The patient with altered mental status will probably interpret the phrase literally or merely rephrase the words.

Association. Another higher level of intellectual functioning involves finding similarities or associations between concepts: a dog is to a beagle as a cat is to a Siamese. Name related concepts, and ask the patient to identify their associations. Questions are appropriate to the patient's level of intelligence. Using simple concepts is sufficient.

Judgement. Judgement requires a comparison and evaluation of facts and ideas to understand their relationships and to form appropriate conclusions. Attempt to measure the patient's ability to make logical decisions with questions such as "Why did you seek health care?" or "What would you do if you became ill at home?" Normally a patient makes logical decisions.

Cranial Nerve Function

A physical examination can involve the assessment of all 12 cranial nerves or a single nerve or related group of nerves. A dysfunction in one nerve reflects an alteration at some point along the distribution of the cranial nerve. Measurements used to assess the integrity of organs within the head and neck also assess cranial nerve function. A complete assessment involves testing the 12 cranial nerves in order of their numbers. To remember the order of the nerves, use this simple phrase: "On old Olympus' towering tops, a Finn and German viewed some hops." The first letter of each word in the phrase is the same as the first letter of the names of the cranial nerves listed in order (Table 31-37).

Sensory Function

The sensory pathways of the central nervous system conduct sensations of pain, temperature, position, vibration, and crude and finely localized touch. Different nerve pathways relay the sensations. Most patients require only a quick screening of sensory function unless there are symptoms of reduced sensation, motor impairment, or paralysis.

safety alert The risk of skin breakdown is greater in a patient with impaired sensation. When assessing decreased sensation, complete a skin and tissue assessment of the area affected by the sensory loss. In addition, teach the patient to avoid pressure, thermal, and/or chemical trauma to the area.

Normally a patient has sensory responses to all stimuli that are tested. A patient feels sensations equally on both sides of the body in all areas. Assess the major sensory nerves by knowing the sensory dermatome zones (Figure 31-73). Some areas of the skin are innervated by specific dorsal root cutaneous nerves. For example, if assessment reveals reduced sensation when checking for light touch along an area of the skin (e.g., the lower neck), this determines, in general, where a neurological lesion exists (e.g., fourth cervical spinal cord segment).

Perform all sensory testing with the patient's eyes closed so that the patient is unable to see when or where a stimulus strikes the skin (Table 31-38). Then apply stimuli in a random,

► TABLE 31-37 Cranial Nerve Function and Assessment

Number	Name	Type	Function	Method
I	Olfactory	Sensory	Sense of smell	Ask patient to identify different nonirritating aromas such as coffee and vanilla.
II	Optic	Sensory	Visual acuity	Use Snellen chart, or ask patient to read printed material while wearing glasses.
III	Oculomotor	Motor	Extraocular eye movement	Assess directions of gaze.
IV	Trochlear	Motor	Pupil constriction and dilation Upward and downward movement of eyeball	Measure pupillary reaction to light reflex and accommodation. Assess directions of gaze.
V	Trigeminal	Sensory and motor	Sensory nerve to skin of face	Lightly touch cornea with wisp of cotton. Assess corneal reflex. Measure sensation of light pain and touch across skin of face.
VI	Abducens	Motor	Motor nerve to muscles of jaw	Palpate temples as patient clenches teeth.
VII	Facial	Sensory and motor	Lateral movement of eyeballs Facial expression	Assess directions of gaze. As patient smiles, frowns, puffs out cheeks, and raises and lowers eyebrows, look for asymmetry.
VIII	Auditory	Sensory	Taste	Have patient identify salty or sweet taste on front of tongue.
IX	Glossopharyngeal	Sensory and motor	Hearing Taste	Assess ability to hear spoken word. Ask patient to identify sour or sweet taste on back of tongue.
X	Vagus	Sensory and motor	Ability to swallow Sensation of pharynx	Use tongue blade to elicit gag reflex. Ask patient to say "ah." Observe movement of palate and pharynx.
XI	Spinal accessory	Motor	Movement of vocal cords Movement of head and shoulders	Assess speech for hoarseness. Ask patient to shrug shoulders and turn head against passive resistance.
XII	Hypoglossal	Motor	Position of tongue	Ask patient to stick out tongue to midline and move it from side to side.

Figure 31-73 Dermatomes of the body, the body surface areas innervated by particular spinal nerves; C1 usually has no cutaneous distribution. **A**, Anterior view. **B**, Posterior view. It appears that there is a distinct separation of surface area controlled by each dermatome, but there is almost always overlap between spinal nerves. **Source:** From Seidel, H. M., et al. (2011). *Mosby's guide to physical examination* (7th ed., p. 708). St Louis, MO: Mosby.

► TABLE 31-38 Assessment of Sensory Nerve Function

Function	Equipment	Method	Precautions
Pain	Broken tongue blade or wooden end of cotton applicator	Ask patients to voice when they feel dull or sharp sensation. Alternately apply sharp and blunt ends of tongue blade to skin's surface. Note areas of numbness or increased sensitivity.	Remember that areas where skin is thick, such as heel or sole of foot, are less sensitive to pain.
 			
		Assessing sensory nerve function in foot	Assessing sensory nerve function in face
Temperature	Two test tubes, one filled with hot water and other with cold	Touch skin with tube. Ask patient to identify hot or cold sensation.	Omit test if pain sensation is normal.
Light touch	Cotton ball or cotton-tip applicator	Apply light wisp of cotton to different points along skin's surface. Ask patients to voice when they feel a sensation.	Apply at areas where skin is thin or more sensitive (e.g., face, neck, inner aspect of arms, top of feet and hands).
Vibration	Tuning fork	Apply stem of vibrating fork to distal interphalangeal joint of fingers and interphalangeal joint of great toe, elbow, and wrist. Have patients voice when and where they feel vibration.	Be sure patient feels vibration and not merely pressure.
Position		Grasp finger or toe, holding it by its sides with thumb and index finger. Alternate moving finger or toe up and down. Ask patient to state when finger is up or down. Repeat with toes.	Avoid rubbing adjacent appendages as you move finger or toe. Do not move joint laterally; return to neutral position before moving again.
Two-point discrimination	Two broken tongue blades	Lightly apply one or both tongue blade tips simultaneously to the skin's surface. Ask patients whether they feel one or two pricks. Find the distance at which patient can no longer distinguish two points.	Apply blade tips to same anatomical site (e.g., fingertips, palm of hand, or upper arms). Minimum distance at which patient discriminates two points varies (2 to 8 mm on fingertips).

unpredictable order to maintain the patient's attention and prevent detection of a predictable pattern. Ask the patient to describe when, what, and where he or she feels each stimulus. Compare symmetrical areas of the body while applying stimuli to the patient's arms, trunk, and legs.

Motor Function

An assessment of motor function includes measurements made during the musculoskeletal examination. In addition, you assess cerebellar function. The cerebellum coordinates muscular activity, maintains balance and equilibrium, and controls posture.

Coordination. To avoid confusion, demonstrate each manoeuvre and then have the patient repeat it, observing for

smoothness and balance in the patient's movements (Box 31-33). In older adults, normally slow reaction time causes movements to be less rhythmical.

To assess fine motor function, have the patient extend the arms out to the sides and touch each forefinger alternately to the nose (first with eyes open, then with eyes closed). Normally the patient alternately touches the nose smoothly. Performing rapid, rhythmical, alternating movements demonstrates coordination in the upper extremities. While sitting, the patient begins by patting the knees with both hands. Then the patient alternately turns up the palm and back of the hands while continuously patting the knees. Normally patients perform the manoeuvre smoothly and regularly with increasing speed.

BOX 31-33 PATIENT TEACHING

Neurological Assessment

Objectives

- Patient's family will understand relationship of patient's behavioural and mental changes to physical status.
- Patient with sensory or motor impairment will select safety measures for self-care.
- Older adult will routinely inspect skin for injuries.

Teaching Strategies

- Explain to family or friends the implications of any behavioural or mental impairment shown by patient.
- If patient has sensory or motor impairments, explain measures to ensure safety (e.g., use of ambulation aids or safety bars in bathrooms or stairways).
- Teach older adult to plan enough time to complete tasks because reaction time is slow.
- Teach older adult to observe skin surfaces for areas of trauma, because perception of pain is reduced.

Evaluation

- Ask family to discuss patient behaviours that result from neurological impairments.
- Have patient explain safety measures used to avoid injury from sensory and motor limitations.
- Have older patient explain reason for inspecting skin surface routinely.

Figure 31-74 Pathway of the reflex arc.

An additional manoeuvre for upper extremity coordination involves touching each finger with the thumb of the same hand in rapid sequence. The patient moves from the index finger to the little finger and back, with one hand tested at a time. The patient's dominant hand is slightly less awkward when performing this movement. Movement is smooth and in succession.

Test lower extremity coordination with the patient lying supine, legs extended. Place a hand at the ball of the patient's foot. The patient taps the hand with the foot as quickly as possible. Test each foot for speed and smoothness. The feet do not move as rapidly or evenly as the hands.

Balance. Use one or two of the following tests to assess balance and gross motor function:

- Have the patient perform a Romberg test by standing with feet together, arms at the sides, both with eyes open and eyes closed. Protect the patient's safety by standing at the side, observe for swaying. Expect slight swaying of the body in the Romberg test. A loss of balance (positive Romberg) causes a patient to fall to the side. Normally the patient does not break the stance.
- Have the patient close the eyes, with arms held straight at the sides, and stand on one foot and then the other. Normally patients are able to maintain balance for five seconds with slight swaying.
- Ask the patient to walk a straight line by placing the heel of one foot directly in front of the toes of the other foot.

safety alert When examining the older adult patient's gait, be aware of the risk for falls. Some older adult patients need assistance with this portion of the examination.

Reflexes

Eliciting reflex reactions provides data about the integrity of sensory and motor pathways of the reflex arc and specific spinal cord segments. Assessment of reflexes does not determine higher neural centre functioning. Figure 31-74 traces the pathway of the reflex arc. Each muscle contains a small sensory unit called a muscle spindle, which controls muscle tone and detects changes in the length of muscle fibres. Tapping a tendon with a reflex hammer stretches the muscle and tendon, lengthening the spindle. The spindle sends nerve impulses along afferent nerve pathways to the dorsal horn of the spinal cord segment. Within milliseconds, the impulses reach the spinal cord and synapse to travel to the efferent motor neuron in the spinal cord. A motor nerve sends the impulses back to the muscle, causing the reflex response.

The two categories of normal reflexes are deep tendon reflexes, elicited by mildly stretching a muscle and tapping a tendon, and cutaneous reflexes, elicited by stimulating the skin superficially. Grade reflexes are as follows (Jarvis et al., 2009):

- 0 No response
- 1+ Sluggish or diminished
- 2+ Active or expected response
- 3+ More brisk than expected, slightly hyperactive
- 4+ Brisk and hyperactive with intermittent or transient clonus

When assessing reflexes, have the patient relax as much as possible to avoid voluntary movement or tensing of muscles. Position the limbs to slightly stretch the muscle being tested. Hold the reflex hammer loosely between the thumb and fingers so that it is able to swing freely and tap the tendon briskly (Figure 31-75). Compare the responses on corresponding sides. Normally the older adult presents with diminished reflexes. Reflexes are hyperactive in patients with alcohol, cocaine, or opioid intoxication (Caulker-Burnett, 1994). Stick figures are

► TABLE 31-39 Assessment of Common Reflexes

Type	Procedure	Normal Reflex
Deep Tendon Reflexes		
Biceps	Flex patient's arm up to 45 degrees at elbow with palms down. Place your thumb in antecubital fossa at base of biceps tendon and your fingers over biceps muscle. Strike triceps tendon with reflex hammer.	Flexion of arm at elbow
Triceps	Flex patient's arm at elbow, holding arm across chest, or hold upper arm horizontally and allow lower arm to go limp. Strike triceps tendon just above elbow.	Extension at elbow
Patellar	Have patient sit with legs hanging freely over side of table or chair, or have patient lie supine and support knee in a flexed 90-degree position. Briskly tap patellar tendon just below patella.	Extension of lower leg
Achilles	Have patient assume same position as for patellar reflex. Slightly dorsiflex patient's ankle by grasping toes in palm of your hand. Strike Achilles tendon just above heel at ankle malleolus.	Plantar flexion of foot
Cutaneous Reflexes		
Plantar	Have patient lie supine with legs straight and feet relaxed. Take handle end of reflex hammer and stroke lateral aspect of sole from heel to ball of foot, curving across ball of foot toward big toe.	Plantar flexion of all toes
Gluteal	Have patient assume side-lying position. Spread buttocks apart and lightly stimulate perineal area with cotton applicator.	Contraction of anal sphincter
Abdominal	Have patient stand or lie supine. Stroke abdominal skin with base of cotton applicator over lateral borders of rectus abdominis muscle toward midline. Repeat test in each abdominal quadrant.	Contraction of rectus abdominis muscle with pulling of umbilicus toward stimulated side

Figure 31-75 Position for eliciting the patellar tendon reflex. The lower leg normally extends.

sometimes used to record reflexes. Table 31-39 summarizes common deep tendon and cutaneous reflexes.

After the Examination

Record findings from the physical assessment during the examination or at the end. Special forms are available to record data. Review all findings before assisting the patient with dressing, in case of a need to recheck any information or gather additional data. Integrate physical assessment findings into the plan of care.

After completing the assessment, give the patient time to dress. The hospitalized patient sometimes needs help with hygiene and returning to bed. When the patient is

comfortable, it helps to share a summary of the assessment findings. If the findings have revealed serious abnormalities, such as a mass or highly irregular heart rate, consult the patient's health care provider before revealing any findings. It is the health care provider's responsibility to make definitive medical diagnoses. Explain the type of abnormality found and the need for the health care provider to conduct an additional examination.

When cleaning the examination area, use infection-control practices in removing materials or instruments soiled with potentially infectious wastes. If the patient's bedside was the examination site, clear away soiled items from the bedside table, and make sure that the bed linen is dry and clean. The patient will appreciate a clean gown and the opportunity to wash the face and hands. Afterward, be sure to perform hand hygiene.

Be sure to record a complete assessment. If you delayed entering any items into the assessment form, record them at this time to avoid forgetting any important information. If you made entries periodically during the examination, review them for accuracy and thoroughness. Communicate significant findings to appropriate medical and nursing personnel, either verbally or in the patient's written care plan.

The patient often needs a number of ancillary examinations, such as X-ray examinations, laboratory tests, or ultrasonography, after a physical examination. The tests provide additional screening information to rule out the presence of abnormalities and help in the diagnosis of specific abnormalities found during the examination. Explain the purpose of these tests and the sensations that the patient will experience.

Integration of Physical Assessment With Nursing Care

Learn to integrate an examination during routine patient care. For example, assess the condition of the skin during a

bed bath, or observe a patient's gait, ROM, and balance as the patient ambulates. Assisting with activities of daily living offers an additional opportunity to obtain cognitive assessment data. This practice makes more efficient use of time and decreases anxiety involved in formal physical assessment examinations.

❖ KEY CONCEPTS

- Baseline assessment findings reflect the patient's functional abilities and serve as the basis for comparison with subsequent assessment findings.
- Physical assessment of a child or infant requires the application of the principles of growth and development.
- Recognize that the normal process of aging affects physical findings collected from an older adult.
- Integrate patient teaching throughout the examination to help patients learn about health promotion and disease prevention.
- Inspection requires good lighting, full exposure of the body part, and a careful comparison of the part with its counterpart on the opposite side of the body.
- Palpation involves the use of parts of the hand to detect different types of physical characteristics.
- Use auscultation to assess the character of sounds created in various body organs.
- Perform a physical examination only after proper preparation of the environment and equipment and after preparing the patient physically and psychologically.
- Throughout the examination keep the patient warm, comfortable, and informed of each step of the process.
- A competent examiner is systematic while combining assessment of different body systems simultaneously.
- Information from the history helps to focus on body systems likely to be affected.
- When assessing a seriously ill patient, concentrate on the body systems most likely to be affected.
- Creating a mental image of internal organs in relation to external anatomical landmarks enhances accuracy in assessing the thorax, heart, and abdomen.
- When assessing heart sounds, imagine events occurring during the cardiac cycle.
- Never palpate the carotid arteries simultaneously.
- When examining a woman's breasts, explain the techniques for breast self-examination.
- The abdominal assessment differs from other portions of the examination in that auscultation follows inspection.
- During assessment of the genitalia, explain the technique for genital self-examination.
- Conduct an assessment of musculoskeletal function when observing the patient ambulate or participate in other active movements.
- Assess mental and emotional status by interacting with the patient throughout the examination.
- At the end of the examination, provide for the patient's comfort, and then document a detailed summary of physical assessment findings.

❖ CRITICAL THINKING EXERCISES

You are caring for Mrs. Brown, a 75-year-old woman of First Nations ancestry who underwent repair of right fractured femur attributed to osteoporosis. Mrs. Brown was transferred to your hospital from the health centre in her small rural home community. This is her first postoperative day on your clinical unit. The

night nurse reported that the patient had an "uneventful" night. She has an intravenous line (IV) for fluids and medication, a right hip dressing, a Jackson-Pratt drain, a Foley (urethral) catheter to gravity and is on bed rest.

1. What body systems would you assess for this patient?
 - a. Describe the key elements in these assessments.
2. Upon entrance to the room, you observe that Mrs. Brown appears agitated and confused. How do you further evaluate her mental status? What condition may these symptoms indicate?
3. After you reorient Mrs. Brown, she allows you to continue with your assessment. On auscultation of her posterior lung field bases, you hear a crackling noise on inspiration. What is this sound, and what does it indicate?
4. You next assess her cardiac status. Her apical heart rate is 72 beats per minute, rhythm regular. You interpret this finding as
 - a. Abnormal
 - b. Bradycardia
 - c. Normal
 - d. Tachycardia
5. You are performing neurovascular checks of the lower extremities. Describe how you would evaluate for capillary refill.
6. How will you demonstrate cultural competency in your care and assessment of Mrs. Brown?

❖ REVIEW QUESTIONS

1. The nurse conducts a general survey on an adult patient, which includes
 1. Appearance and behaviour
 2. Measurement of vital signs
 3. Observing specific body systems
 4. Conducting a detailed health history
2. To correctly palpate the patient's skin for temperature, the nurse uses the
 1. Base of the hands
 2. Fingertips of the hands
 3. Dorsal surface of the hands
 4. Palmar surface of the hands
3. To assess a patient's superficial lymph nodes, the nurse
 1. Deeply palpates using the entire hand
 2. Lightly palpates using a bimanual technique
 3. Deeply palpates using a bimanual technique
 4. Gently palpates using the pads of the index and middle fingers
4. The nurse is teaching the patient to inspect all skin surfaces and to report pigmented skin lesions that
 1. Are symmetrical
 2. Are uniform in colour
 3. Have irregular borders
 4. Are less than 6 mm in diameter
5. To auscultate the patient's lung fields, the nurse uses a systematic pattern comparing
 1. Top to bottom
 2. Anterior to posterior
 3. Side to side
 4. Interspace to interspace

6. The patient's respiratory assessment reveals a loud, low-pitched, rumbling coarse sound heard during inspiration and expiration. The nurse interprets these sounds as
 1. Crackles
 2. Normal
 3. Rhonchi
 4. Wheezes
7. While auscultating heart sounds, the nurse documents that S_2 is best heard at the base. This sound (S_2) correlates with closure of the
 1. Aortic and mitral valves
 2. Mitral and tricuspid valves
 3. Aortic and pulmonic valves
 4. Tricuspid and pulmonic valves
8. To assess the patient's dorsalis pedis pulse, the nurse palpates
 1. Behind the knee
 2. Over the lateral malleolus
 3. In the groove behind the medial malleolus
 4. Lateral to the extensor tendon of the great toe
9. To spread breast tissue evenly over the chest wall during an examination, the nurse asks the patient to lie supine with
 1. Both arms overhead with palms upward
 2. Hands clasped just above the umbilicus
 3. The dominant arm straight alongside the body
 4. The ipsilateral arm overhead with a small pillow under the shoulder
10. Place in order the assessment techniques employed during an abdominal examination.
 1. Palpation
 2. Inspection
 3. Percussion
 4. Auscultation
11. The nurse is teaching a patient how to perform a testicular self-examination. The nurse informs the patient:
 1. "The testes are normally round, movable, and have a lumpy consistency."
 2. "Contact your health care provider if you feel a painless pea-sized nodule."
 3. "The best time to do a testicular self-examination is before your bath or shower."
 4. "Perform a testicular self-examination weekly to detect signs of testicular cancer."
12. The patient is being assessed for range of joint movement. You ask the patient to move the arm toward the body, evaluating the movement of
 1. Flexion
 2. Extension
 3. Abduction
 4. Adduction
13. The nurse asks the patient to interpret the saying "Don't count your chickens before they're hatched." The patient's response reveals
 1. Judgement
 2. Knowledge
 3. Association
 4. Abstract reasoning
14. The nurse asks the patient to shrug the shoulders and turn the head side to side against the resistance of the examiner's hand; these actions evaluate cranial nerve number
 1. VII-facial
 2. V-trigeminal
 3. XII-hypoglossal
 4. XI-spinal accessory
15. The nurse recognizes all of the following as common biocultural variations of normal physical exam findings except
 1. Darker skin creases on the body of a patient with a dark complexion
 2. Dry, flaky cerumen in the ear canal of a child of First Nations descent
 3. Elevated blood pressure in an individual of African ancestry
 4. Dark brown areolae in a fair-complexioned woman aged 45 years
16. When positioning a patient who has had a left total hip replacement, the nurse is aware that extra care must be taken if placing the patient in the _____ position.
 1. Lateral recumbent
 2. Lithotomy
 3. Dorsal recumbent
 4. Sims'

Infection Control

Original chapter by Ruth M. Curchoe, RN, MSN, CIC

Canadian content written by Colleen M. Astle, RN, BScN, MN,
and Deborah Hobbs, RN, BScN, CIC

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Explain the relationship between the chain of infection and the transmission of infection.
- Identify the body's normal defences against infection.
- Discuss the events in the inflammatory response.
- Describe the signs and symptoms of a localized and a systemic infection.
- Identify patients most at risk for infection.
- Explain conditions that promote the transmission of health care-associated infection.
- Explain the difference between medical and surgical asepsis.
- Give an example of preventing infection for each element of the infection chain.
- Perform proper procedures for hand hygiene.
- Explain the rationale and components of routine practices.
- Explain the rationale and practices for additional (isolation) precautions.
- Explain how infection-control measures in the home may differ from those in the hospital.
- Properly don a surgical mask, sterile gown, and sterile gloves.

Good health depends in part on a safe environment. Practices or techniques that control or prevent transmission of infection help to create an environment that protects patients and health care workers from disease. Patients in all health care settings are at risk for acquiring infections because they often have lower resistance to infectious **microorganisms** and increased exposure to numbers and types of disease-causing microorganisms, and they sometimes undergo **invasive** procedures wherein a body cavity or organ is entered by either puncture or incision. Microorganisms can only be seen with the aid of a microscope and are typically a single cell. They include bacteria, protozoans, certain types of algae, and fungi. In acute care or ambulatory care facilities,

patients can be exposed to pathogens, some of which may be resistant to most antibiotics. By practising infection prevention and control techniques, you can avoid spreading microorganisms to patients.

In all settings, patients and their families must be able to recognize sources of infections and be able to institute protective measures. Patient teaching should include information concerning infections, modes of transmission, and methods of prevention.

Health care workers can protect themselves from contact with infectious materials or exposure to communicable diseases by having knowledge of the infectious process and appropriate barrier protections. The spread of diseases such as hepatitis B and C, acquired immune deficiency syndrome (AIDS), sudden acute respiratory syndrome (SARS), and tuberculosis have resulted in a greater emphasis on infection control techniques. Infection control has two purposes: (1) protecting patients from acquiring infections and (2) protecting health care workers from becoming infected. Many of the techniques used to protect patients also provide effective protection for nurses. You must remain constantly vigilant to prevent the spread of infection while providing care.

Scientific Knowledge Base

Microorganisms live and grow on inanimate objects and in air, water, food, soil, plants, and animals. They also live and grow in and on people. Most microorganisms are nonpathogens, meaning that they do not cause a person to be ill; however, some are **pathogens**, meaning that they are capable of causing disease. An infection is a disease state resulting from the entry and multiplication of a pathogen in the tissues of a host causing the body to manifest clinical signs and symptoms. If the infection can be transmitted from one person to another, it is a **communicable** (infectious, contagious) disease. Resident skin microorganisms are usually nonpathogenic. However, they can cause serious infection when surgery or other invasive procedures allow them to enter deep tissues, or when a patient is severely **immunocompromised** (has an impaired immune system).

Chain of Infection

The presence of a pathogen does not mean that an infection will begin. The development of an infection occurs in a cycle that depends on the presence of all the following elements:

- An infectious agent (pathogen)
- A reservoir (source for pathogen growth)
- A portal of exit from the reservoir
- A mode of transmission
- A portal of entry to a host
- A susceptible host

An infection develops if this chain remains intact (Figure 32-1). You will follow infection prevention and control practices to break the chain so that infections do not develop.

Infectious Agents. Microorganisms include bacteria, viruses, fungi, and protozoa (Table 32-1). Microorganisms on the skin are called resident or *transient flora*. Resident organisms are considered permanent residents of the skin, where they survive and multiply without causing harm. They are not easily removed by handwashing with plain soaps unless considerable friction is used. Resident microorganisms in deep skin layers are usually killed only by performing hand hygiene with products containing antimicrobial ingredients.

Figure 32-1 Chain of infection.

Transient microorganisms attach to the skin when a person has contact with another person or object. For example, when you touch a bedpan or a contaminated dressing, transient bacteria adhere to your skin. The organisms attach loosely to the skin in dirt and grease and under fingernails. These organisms may be readily transmitted unless removed by handwashing/hand hygiene (Centers for Disease Control and Prevention [CDC], 2007; Wilson, 2006, p. 75).

The potential for microorganisms to cause disease depends on the following factors:

- A sufficient number of organisms
- **Virulence**, or the ability to produce disease
- The ability to enter and survive in the host
- The susceptibility of the host

Reservoir. A reservoir is a place where a pathogen can survive but may or may not multiply. For example, hepatitis A virus survives in shellfish but does not multiply; *Pseudomonas* organisms can survive and multiply in nebulizer reservoirs used in the care of patients with respiratory problems. The most common reservoir is the human body. A variety of microorganisms live on the skin and within body cavities, fluids, and discharges. When a pathogen is present on or in the body but does not cause harm, the pathogen is **colonizing** the site. **Carriers** are animals or persons who show no symptoms of illness but who have pathogens on or in their bodies that can be transferred to others. For example, a person can be a carrier of hepatitis B virus without having any signs or symptoms of infection. Animals, food, water, insects, and even inanimate objects can also be reservoirs for infectious organisms. For example, the bacterium *Legionella pneumophila*, which causes legionnaires' disease, lives in contaminated water and water systems. To thrive, pathogens require a reservoir that provides food, oxygen (or no oxygen, depending on the pathogen), water, an appropriate temperature and pH, and minimal light.

Food. Microorganisms require nourishment. Some—such as *Clostridium perfringens*, the microbe that causes gas gangrene—thrive on organic matter. Others, such as *Escherichia coli*, consume undigested food in the bowel. Carbon dioxide and inorganic materials such as soil provide nourishment for other organisms.

► TABLE 32-1 Common Pathogens and Resulting Major Infections

Organism	Major Reservoir(s)	Major Infections
Bacteria		
<i>Clostridium difficile</i>	Colon	Colitis, diarrhea
<i>Escherichia coli</i>	Colon	Gastroenteritis, urinary tract infection
<i>Staphylococcus aureus</i>	Skin, hair, anterior nares	Wound infection, pneumonia, food poisoning, cellulitis, bacteremia, meningitis, osteomyelitis, septic arthritis
<i>Streptococcus</i> (β -hemolytic group A) organisms	Oropharynx, skin, perianal area	"Strep throat," rheumatic fever, scarlet fever, impetigo, wound infection, glomerulonephritis (Gladwin & Trattler, 2003, p. 23)
<i>Streptococcus</i> (β -hemolytic group B) organisms	Adult genitalia	Urinary tract infection, wound infection, postpartum sepsis, neonatal sepsis
<i>Mycobacterium tuberculosis</i>	Droplet nuclei from lungs	Tuberculosis
<i>Neisseria gonorrhoeae</i>	Genitourinary tract, rectum, mouth	Gonorrhea, pelvic inflammatory disease, infectious arthritis, conjunctivitis
<i>Rickettsia rickettsii</i>	Wood tick	Rocky Mountain spotted fever
<i>Staphylococcus epidermidis</i>	Skin	Wound infection, bacteremia
Viruses		
Hepatitis A virus	Feces	Hepatitis A
Hepatitis B virus	Blood and body fluids	Hepatitis B
Hepatitis C virus	Blood	Hepatitis C
Herpes simplex virus (type 1)	Lesions of mouth or skin, saliva, genitalia	Cold sores, aseptic meningitis, genital herpes, herpetic whitlow
Human immunodeficiency virus	Blood, semen, vaginal secretions, breast milk (has also been isolated in saliva, tears, and urine, but these have not proved to be sources of transmission)	Acquired immune deficiency syndrome
Fungi		
<i>Aspergillus</i> organisms	Soil, dust, construction dust, decaying or organic matter	Sinusitis or skin, lung, wound, or central nervous system infection (Wilson, 2006)
<i>Candida albicans</i>	Mouth, skin, colon, genital tract	Candidiasis, pneumonia, sepsis
Protozoan		
<i>Plasmodium falciparum</i>	Blood	Malaria

Oxygen. Aerobic bacteria require oxygen to survive and to multiply sufficiently to cause disease. Aerobic organisms cause more infections than do **anaerobic** organisms (i.e., organisms that can survive only in the absence of oxygen). Examples of aerobic organisms are *Staphylococcus aureus* and strains of *Streptococcus* organisms.

The gastrointestinal tract is colonized by large numbers of anaerobic bacteria that can cause infections if the bowel is damaged. Infections deep within the pleural cavity, in a joint, or in a deep sinus tract are typically caused by anaerobes. Bacteria that cause tetanus, gas gangrene, and botulism are anaerobes.

Water. Most organisms require water or moisture for survival. For example, microorganisms thrive in the moist drainage from a surgical wound. However, some bacteria assume a form called a *spore*. Spores remain viable even when deprived of water and are resistant to drying. Spore-forming bacteria, such as those that cause anthrax, botulism, and tetanus, can live without water.

Temperature. Microorganisms can live only in certain temperature ranges. The ideal temperature for most pathogens in humans is 35 to 37°C; however, some can survive temperature extremes that would be fatal to humans (Wilson, 2006,

p. 12). Cold temperatures tend to prevent the growth and reproduction of bacteria.

pH. The acidity of an environment determines the viability of microorganisms. Most microorganisms prefer an environment within a pH range of 5 to 8. Bacteria, in particular, thrive in urine with an alkaline pH. Most organisms cannot survive the acidic environment of the stomach. In patients receiving acid-reducing medications (e.g., antacids and histamine 2 blockers), these can cause an overgrowth of gastrointestinal organisms, which can contribute to nosocomial pneumonia (CDC, 2004).

Minimal Light. Microorganisms thrive in dark environments such as those under dressings and within body cavities. Ultraviolet light may be effective in killing certain forms of bacteria (e.g., *Mycobacterium tuberculosis*).

Portal of Exit. After microorganisms find a site in which to grow and multiply, they must find a portal of exit if they are to enter another host and cause disease. A *portal of exit* is the path by which the pathogen leaves the reservoir (Sorrentino, 2009). Exits in the human body include body openings (mouth, nose, rectal, vaginal, and urethral openings; and artificial openings such as those resulting from ostomies), breaks in the skin (a scrape, cut, or other wound), and breaks in the mucous

membranes (the skin in the mouth, eyes, nose, vagina, and rectum). Pathogens are carried through portals of exit by blood, body fluids, excretions, and secretions (e.g., urine, stool, vomitus, saliva, mucus, pus, vaginal discharge, semen, wound drainage, bile, and sputum). For example, pathogens that infect the respiratory tract, such as *M. tuberculosis*, can be released from the body through the mouth and nose when an infected person sneezes, coughs, talks, or even breathes. In patients with artificial airways such as tracheostomy or endotracheal tubes (see Chapter 38), organisms easily exit the respiratory tract through these devices. Similarly, when a patient has a urinary tract infection, microorganisms exit during urination or through urinary diversions such as ileal conduits, urostomies, and suprapubic drains (see Chapter 43).

Modes of Transmission. Microorganisms can be transmitted from the reservoir to the host in many ways. Certain infectious diseases tend to be transmitted more commonly by specific modes (Table 32-2). However, a microorganism may be transmitted by more than one mode. For example, human

chicken pox virus may be spread by the airborne route or through direct contact.

Indirect contact is a major mode of transmission in health care facilities. The health care worker's hands can easily pick up microbes from one person, place, or thing and then transmit them to other people, places, or things. However, almost any object within the environment (e.g., a stethoscope or thermometer) can be a mode of indirect transmission of pathogens. Some organisms, such as *Clostridium difficile*, which can produce spores, can live in hospital environments for months. *C. difficile* can be spread by direct or indirect contact. All health care workers providing direct care (e.g., nurses, physiotherapists, and physicians) or performing diagnostic and support services (e.g., laboratory technicians, respiratory therapists, and dietary workers) must follow practices to minimize the spread of infection. Each group follows procedures for handling equipment and supplies used by a patient. For example, respiratory therapists perform hand hygiene before working with each patient and dispose of contaminated

► TABLE 32-2 Modes of Transmission

Mode of Transmission

Contact Transmission

The transfer of microbes by physical touch; may be by direct contact, indirect contact, or droplet

Direct Contact

Physical skin-to-skin contact between an infected or colonized individual and a susceptible host (e.g., via touching patient)

Indirect Contact

Contact between a susceptible host and a contaminated intermediate object (e.g., via touching soiled linen, equipment, or dressings; transferring pathogens to a patient via hands that are not washed between handling patients)

Droplet Transmission

Large particles (droplets) from the respiratory system of an infected source propelled up to 1 m through the air and deposited onto a susceptible host (e.g., droplets produced via coughing, sneezing, or talking)

Airborne Transmission

Small airborne particles (droplet nuclei) containing microbes remain suspended in the air for long periods of time (e.g., droplets and aerosolized airborne particles produced via coughing and sneezing); air currents transmit these particles long distances (>1 m); susceptible host inhales them

Vehicle Transmission

A single contaminated source (e.g., water, drugs, intravenous fluid, food, equipment) transmits infection to multiple hosts, possibly resulting in an outbreak

Vectorborne Transmission

Insects (fleas, mites, ticks, mosquitoes) or pests (e.g., mice) transmit microbes to humans

Examples of Organisms

Direct: *Clostridium difficile*; methicillin-resistant

Staphylococcus aureus (MRSA); vancomycin-resistant enterococci (VRE)

Indirect: MRSA, VRE; *Pseudomonas*; multidrug-resistant *Acinetobacter*

Droplet: Influenza virus, rubella virus, sudden acute respiratory syndrome

Clostridium difficile; *Staphylococcus*, herpes simplex virus, MRSA, VRE, multidrug-resistant *Acinetobacter*

Clostridium difficile; *Staphylococcus*, respiratory syncytial virus, *Pseudomonas*, MRSA, VRE, multidrug-resistant *Acinetobacter*

Influenza virus, rubella virus, sudden acute respiratory syndrome virus (RSV)

Mycobacterium tuberculosis (causes tuberculosis), varicella-zoster virus; causes chicken pox), measles virus

Pseudomonas (via water, drugs), *Escherichia coli* (via food, water), *Enterobacter cloacae* (via IV fluid), *Salmonella* (via food)

Vibrio cholerae, *Plasmodium falciparum* (causes malaria), West Nile virus, Lyme disease

therapy equipment in a prescribed manner. Certain medical devices and diagnostic procedures provide avenues for the spread of pathogens. Invasive procedures such as cystoscopy (the use of an endoscope to visualize the bladder) facilitate the diagnosis of problems but also increase the risk of infection transmission. Because so many factors can promote the spread of infection to a patient, all health care workers must be conscientious about using infection control practices, such as proper handwashing and ensuring that equipment has been adequately disinfected or sterilized.

Portal of Entry. Organisms can enter the body through the same routes they use to exit (i.e., body openings and breaks in the skin or mucous membranes). For example, organisms enter the body when a needle pierces the skin. As long as the device is in place, more organisms are able to enter the body. In patients with a urinary catheter, any obstruction to the flow of urine allows organisms to travel up the urethra. Factors that reduce the body's defences enhance the chances of pathogens entering the body.

Susceptible Host. Whether a person acquires an infection is related to his or her susceptibility to an infectious agent—**susceptibility** depends on the individual's degree of resistance to a pathogen. Although everyone is constantly in contact with large numbers of microorganisms, an infection does not develop until an individual becomes susceptible to the strength and numbers of microorganisms capable of producing infection. The more virulent an organism is, the greater the likelihood that a person will be susceptible to it. Organisms with resistance to antibiotics are becoming more common in acute care settings—this is believed to be associated with the frequent and sometimes inappropriate use of antibiotics. A person's resistance to an infectious agent may be enhanced by receiving an appropriate vaccine or actually contracting the disease.

Infectious Process

By understanding the chain of infection, you can intervene to prevent infections from developing. If a patient is at risk for acquiring an infection, you should observe for signs and symptoms of infection and take appropriate actions to prevent its spread. Infections follow a progressive course (Box 32-1). The severity of a patient's illness depends on the extent of the infection, the ability of the microorganism to cause disease (**pathogenicity** of the microorganisms), and the susceptibility of the host (patient).

If infection is **localized**, or restricted to a limited area (e.g., a wound infection), proper care controls the spread and minimizes the illness. The patient may experience localized symptoms such as pain and tenderness at the wound site. An infection that affects the entire body instead of just a single organ or part is **systemic** and can be fatal.

The course of an infection influences the level of nursing care provided. You are responsible for properly administering antibiotics and monitoring the response to drug therapy (see Chapter 33). Supportive therapy includes providing adequate nutrition and rest to bolster the patient's defences against the infectious process. The complexity of care depends on body systems affected by the infection.

Regardless of whether an infection is localized or systemic, you play a critical role in minimizing its spread. For example, an organism causing a simple wound infection can spread to involve an intravenous needle-insertion site if you use an improper technique when changing a dressing at this site.

► BOX 32-1 Course of Infection by Stage

Incubation Period

- Interval between the entrance of pathogen into body and the appearance of first symptoms (e.g., in chickenpox, 2 to 3 weeks; in the common cold, 1 to 2 days; in influenza, 1 to 3 days; in mumps, 15 to 18 days).

Prodromal Stage

- Interval from the onset of nonspecific signs and symptoms (malaise, low-grade fever, and fatigue) to more specific symptoms (during this time, microorganisms grow and multiply and the patient may be more capable of spreading disease to others).

Illness Stage

- Interval when the patient manifests signs and symptoms specific to type of infection (e.g., the common cold is manifested by a sore throat, sinus congestion, and rhinitis; mumps is manifested by an earache, a high fever, and parotid and salivary gland swelling).

Convalescence

- Interval when the acute symptoms of infection disappear and the body tries to replenish its resources and return to a state of homeostasis; the length of recovery depends on the severity of the infection and the patient's general state of health (may take several days to months).

Nurses who have breaks in their own skin can also acquire infections from patients if their techniques for controlling infection transmission are inadequate.

Defences Against Infection

The body has several mechanisms that protect it against infection. Normal body flora that reside inside and outside the body protect a person from several pathogens. Each organ system has defence mechanisms that fight infectious microorganisms. The **immune response** is a protective reaction that neutralizes pathogens and repairs body cells. The immune system is composed of cells and molecules that help the body resist disease; certain responses of the immune system are nonspecific and protect against microorganisms regardless of prior exposure (e.g., normal flora, body system defences, and inflammation), whereas others are specific defences against particular pathogens. If any of the body's defences fail, an infection can quickly progress to a serious health problem.

Normal Flora. The body normally contains microorganisms that reside on the surface and in deep layers of skin, in the saliva and oral mucosa, and in the gastrointestinal and genitourinary tracts. A person normally excretes trillions of microbes daily through the intestines. The skin also has a large population of resident flora—these **normal flora** do not typically cause disease when residing in their usual area of the body but, instead, participate in maintaining health.

Normal flora of the large intestine exist in great numbers without causing injury. They also secrete antibacterial substances within the intestine's walls. The skin's normal flora exert a protective action by inhibiting the multiplication of organisms landing on the skin. The mouth and pharynx are also protected by flora that impair the growth of invading microbes. The mass of normal flora maintains a sensitive balance with other microorganisms to prevent infection. Any

factor that disrupts this balance places a person at increased risk for acquiring an infectious disease. For example, according to studies, when a patient acquires microorganisms within the hospital, the person's resident flora change, which may lead to an infection (Bryant & Nix, 2007, pp. 45–48).

In addition, the use of **broad-spectrum antibiotics** for the treatment of infection can lead to a **superinfection**, which develops when broad-spectrum antibiotics eliminate a wide range of microorganisms, not just those causing infection. Normal bacterial flora are eliminated, reducing the body's defences and, thus, allowing disease-producing microorganisms to multiply (Siegel et al., 2007).

Body System Defences. A number of the body's organ systems have unique defences against infection (Table 32-3). The skin, respiratory tract, and gastrointestinal tract are easily accessible to microorganisms: pathogenic organisms easily adhere to the skin's surface, are inhaled into the lungs, or are ingested with food. Each organ system has defence mechanisms

physiologically suited to its structure and function. For example, the lungs cannot completely control the entrance of microorganisms; however, the airways are lined with hairlike projections (cilia) that rhythmically beat to move a blanket of mucus and adherent or trapped organisms up to the pharynx to be removed. Conditions that impair an organ's specialized defences increase the person's susceptibility to infection.

Inflammation. Inflammation is the body's cellular response to injury or infection. Inflammation is a protective vascular reaction that delivers fluid, blood products, and nutrients to interstitial tissues in an area of injury. The process neutralizes and eliminates pathogens or **necrotic** (dead) tissues and establishes a means of repairing body cells and tissues. Signs of localized inflammation are swelling, redness, heat, pain or tenderness, and loss of function in the affected body part. When infection becomes systemic, other signs and symptoms develop, including fever, leukocytosis, malaise, anorexia, nausea, vomiting, and lymph node enlargement.

► **TABLE 32-3** Normal Defence Mechanisms Against Infection

Defence Mechanisms	Action	Factors That May Alter Defence
Skin		
Intact multilayered surface (body's first line of defence against infection)	Provides barrier to microorganisms and antibacterial activity	Cuts, abrasions, wounds, areas of maceration (softening of the skin due to moisture), burns, or penetration by invasive devices
Shedding of outer layer of skin cells	Removes organisms that adhere to skin's outer layers	Failure to bathe regularly
Sebum	Contains fatty acid that kills some bacteria	Excessive bathing
Mouth		
Intact multilayered mucosa	Provides mechanical barrier to microorganisms	Lacerations, trauma, extracted teeth
Saliva	Washes away particles containing microorganisms, contains microbial inhibitors (e.g., lysozyme)	Poor oral hygiene, dehydration
Eye		
Tearing and blinking	Blinking prevents entry of particles containing pathogens, and tearing helps to wash particles away	Injury
Respiratory Tract		
Cilia lining upper airway, coated with mucus	Trap inhaled microbes and sweep them outward in mucus to be expectorated or swallowed	Smoking, high concentration of oxygen and carbon dioxide, decreased humidity, cold air
Macrophages	Engulf and destroy microorganisms that reach the lung's alveoli	Smoking
Urinary Tract		
Flushing action of urine flow	Washes away microorganisms on lining of bladder and urethra	Obstruction to normal flow by urinary catheter placement, obstruction from growth or tumour, delayed micturition
Intact multilayered epithelium	Provides barrier to microorganisms	Introduction of urinary catheter, continual movement of catheter in urethra
Gastrointestinal Tract		
Acidity of gastric secretions	Acids destroy some microorganisms	Administration of antacids to neutralize acids
Increased peristalsis in small intestine	Prevents retention of bacterial contents	Delayed motility resulting from impaction of fecal contents in large bowel or mechanical obstruction by masses
Vagina		
At puberty, normal flora causing vaginal secretions to achieve low pH	Inhibit growth of many microorganisms	Use of antibiotics or oral contraceptives, which disrupt normal flora

The **inflammatory response** may be triggered by physical agents, chemical agents, or microorganisms. Mechanical trauma, temperature extremes, and radiation are examples of physical agents. Chemical agents include external and internal irritants such as harsh poisons and gastric acid.

After tissues are injured, the inflammatory response, a series of well-coordinated events, occurs:

- Vascular and cellular responses
- The formation of inflammatory **exudates** (fluid and cells that are discharged from cells or blood vessels, e.g., pus or serum)
- Tissue repair

Vascular and Cellular Responses. Acute inflammation is an immediate response to cellular injury. Arterioles supplying the infected or injured area dilate, allowing more blood into the local circulation. The increase in local blood flow causes the characteristic redness of inflammation. The symptom of localized warmth results from a greater volume of blood at the inflammatory site. Local vasodilation enables blood and white blood cells (WBCs) to travel to the injured tissues.

Injury causes tissue necrosis, and, as a result, the body releases histamine, bradykinin, prostaglandin, and serotonin. These chemical mediators increase the permeability of small blood vessels, allowing fluid, protein, and cells to enter interstitial spaces. Accumulated fluid appears as localized swelling (**edema**).

Another symptom of inflammation is pain—the swelling of inflamed tissues increases the pressure on nerve endings, causing pain. Chemical substances such as histamine stimulate nerve endings. As a result of physiological changes occurring with inflammation, the involved body part usually undergoes a temporary loss of function. For example, a localized infection of the hand causes the fingers to become swollen, painful, and discoloured. Joints may become stiff as a result of the swelling, but the function of the fingers returns when inflammation subsides.

The cellular response of inflammation involves WBCs arriving at the site. These cells pass through the blood vessels and into the tissues. Through the process of **phagocytosis**, specialized WBCs, called *neutrophils* and *monocytes*, ingest and destroy microorganisms and other small particles. As inflammation becomes systemic, other signs and symptoms develop. **Leukocytosis**, or an increase in the number of circulating WBCs, is the body's response to WBCs leaving blood vessels. A serum WBC count is normally 5000/mm³ to 10,000/mm³ but may rise to 15,000/mm³ or even higher during inflammation. Fever is caused by the phagocytic release of pyrogens from bacterial cells that cause a rise in the hypothalamic set point (see Chapter 30).

Inflammatory Exudates. The accumulation of fluid, dead tissue cells, and WBCs forms an exudate at the site of inflammation (see Chapter 46). The exudate may be **serous** (clear, watery plasma), **sanguineous** (bloody drainage), **serosanguineous** (thin, watery drainage that is blood tinged), or **purulent** (thick drainage that contains pus). Eventually, the exudate is cleared away through lymphatic drainage. Platelets and plasma proteins such as fibrinogen form a mesh-like matrix at the site of inflammation to prevent the spread of infection.

Tissue Repair. When tissues are injured, healing involves the inflammation, proliferation, and remodelling stages (see Chapter 46). Damaged cells are eventually replaced with healthy new ones, which undergo a gradual maturation until

they take on the same structural characteristics and appearance as the previous cells. However, unless a wound is minor, the healed wound does not usually have the tensile strength of the tissue it replaces and scarring may occur.

Health Care-Associated Infections

Patients in health care settings have an increased risk of acquiring infections. A **health care-associated infection** (HAI), also known as **nosocomial infection** or *iatrogenic infection*, is an infection acquired after admission to a health care facility that was not present or incubating at the time of admission. Patients in hospitals are at risk for infections because they may have a high acuity of illness and frequently undergo aggressive treatments, many of which compromise immunity (CDC, 2007). Transmission of antibiotic-resistant organisms also can occur in health care facilities because a large population of susceptible people who frequently receive antibiotics are in close proximity to each other.

Clostridium difficile infection (CDI) is one of the most common and costly HAIs. *C. difficile* is a Gram positive, spore-forming, anaerobic bacillus that produces two toxins, A and B, which cause diarrhea and colitis in patients whose bacterial flora have been disrupted by prior antibiotic use. Pseudomembranous colitis (PMC) is a more severe form of CDI, in which patients have a colitis characterized by the presence of pseudomembranes on the colon surface seen during endoscopy. Infection control measures to prevent transmission of *C. difficile* to patients include placing the patient on contact isolation, good hand hygiene (usually with soap and water for patients who have diarrhea), gloves and gowns, as well as thorough environmental cleaning. Another important preventative measure is good antibiotic stewardship.

Health care-associated infections can result from a diagnostic or therapeutic procedure, such as a urinary tract infection that develops after catheter insertion. The incidence of nosocomial infections can be reduced if you use critical thinking when practising aseptic techniques. You should always consider the patient's risks for infection and anticipate how the approach to care may increase or decrease the chances of infection transmission (Box 32-2).

HAIs may be exogenous or endogenous. An **exogenous infection** arises from microorganisms external to the individual that do not exist as normal flora; examples are *Salmonella* organisms and *Clostridium tetani*. An **endogenous infection** can occur when some of the patient's flora become altered and overgrowth results. Examples are infections caused by enterococci, yeasts, and streptococci. When sufficient numbers of microorganisms normally found in one body cavity or lining are transferred to another body site, an endogenous infection develops. For example, the transmission of enterococci, normally found in fecal material, from the hands to the skin is a common cause of wound infections. The number of microorganisms needed to cause an infection depends on the virulence of the organism, the host's susceptibility, and the site affected.

A patient's risk of infection is influenced by the number of health care workers having direct contact with the patient, the type and number of invasive procedures, the therapy received, and the length of hospitalization. Major sites for HAI are surgical and traumatic wounds, urinary and respiratory tracts, and the bloodstream (Box 32-3).

Older adults have an increased susceptibility to HAIs because they are more likely to have a chronic disease and

► BOX 32-2 NURSING CARE PLAN

Perils of Central Venous Catheters

Assessment

Susan Serious is a 48-year-old woman in end-stage renal failure secondary to focal segmental glomerulosclerosis, diagnosed two months previously. She is dialysis dependent, which required the insertion of a central venous catheter. Susan was admitted to the nephrology service on Friday evening from the emergency department with complaints of chills, nausea, vomiting, headache, and fatigue. She stated that she had felt well until the end of her dialysis treatment that day.

Susan related that she is allergic to co-trimoxazole (Bactrim). Her medication list is composed of amlodipine (Norvasc), ramipril (Altace), furosemide (Lasix), prednisone, calcium carbonate, multivitamins (Replavite), iron dextran, and darbepoetin alpha (Aranesp).

Assessment Activities

Review signs and symptoms of localized and systemic infections.

Findings and Defining Characteristics

Signs of localized infection include swelling, redness, heat, pain, or tenderness and loss of function in the affected body part.

Signs and symptoms of systemic infection include fever, leukocytosis, malaise, anorexia, nausea, vomiting, and lymph node enlargement.

Research susceptibility to infection in patients with end-stage renal failure.

The literature shows that infections are a significant cause of morbidity and mortality in patients with end-stage renal failure in part due to the clinical setting where treatment is received, the type of dialysis access, and the use of immunosuppressive medications (Berman et al., 2004). Susan has been taking prednisone 30 mg daily.

Review effects of medications.

Prednisone suppresses the body's response to infection.

Nursing Diagnosis: Risk for infection related to disease, immunosuppressive medications, and the use of a central venous catheter.

Planning

Goals

Susan will be treated for infection and will remain free of future infections.

Expected Outcomes

Follow up results of chest radiographs, complete blood count with differential, and blood cultures with attending nephrologist to diagnose and treat existing infection.

Initiate IV antibiotics, as ordered, to treat existing infection.

Arrange to have the tunneled central venous catheter removed for 48 hours while receiving antibiotics as ordered, to eliminate the source of infection. After 48 hours, the catheter may be reinserted using sterile technique.

Susan will recover from existing infection and will not develop signs or symptoms of new infections.

Susan will become knowledgeable of infection risks.

Susan will self-monitor for signs and symptoms of infection, report these to health care providers, and will observe for good aseptic technique during catheter care by the health care providers. Review the use and dosage of prednisone with Susan to increase her understanding of immunosuppressive medications.

Interventions

Prevention and Early Detection

Monitor Susan's temperature and vital signs, and inspect the central venous catheter exit site for evidence of infection.

Rationale

Interventions are designed to prevent and ensure early detection of infection.

Practise hand hygiene before and after catheter care.

Handwashing reduces bacterial counts on hands (CDC, 2007; Health Canada, 2007).

Teach Susan to perform hand hygiene.

Teach Susan about her catheter: aseptic technique, infection rates, care, and indications of infection.

Increased knowledge will aid in the early detection of infection.

Teach Susan about her medications, indications, side effects, and dosages.

Increased knowledge will increase adherence to the medication regimen and reporting of any related issues.

Evaluation

Nursing Actions

Compare Susan's temperature, vital signs, and physical findings with baseline data.

Patient Response and Finding

Susan remains afebrile, free of signs and symptoms of infection.

Achievement of Outcome

Susan has no active infection at this time.

Ask Susan to review knowledge of catheter-related infections.

Susan is able to identify signs and symptoms of catheter-related infections.

Susan has demonstrated a good knowledge base of catheter-related infections.

Continued

► BOX 32-2 NURSING CARE PLAN—cont'd

Nursing Actions	Patient Response and Finding	Achievement of Outcome
Ask Susan to explain the importance of hand hygiene related to catheter care.	Susan is able to relate that hand hygiene eliminates microorganisms that may contribute to infections.	Susan understands the principles and rationale of hand hygiene.
Ask Susan to discuss central venous catheters and the use of aseptic technique during care of the catheters.	Susan is able to describe aseptic technique during catheter care.	Susan has demonstrated knowledge of catheter care.
Ask Susan to review the medications she is currently using.	Susan is able to list and explain the use of her current medications.	Susan has demonstrated an understanding of her medications regarding their use, effects, and potential concerns.

► BOX 32-3

Sites for and Causes of Health Care-Associated Infections

Surgical and Traumatic Wounds

Improper skin preparation (shaving and bathing) before surgery
 Failure to cleanse skin surface properly
 Failure to use aseptic technique during dressing changes
 The use of contaminated antiseptic solutions
 Improper hand hygiene

Urinary Tract

Inappropriate and unsterile catheterization techniques
 Inadequate monitoring of in-dwelling urinary catheters
 Obstruction or blockages in tubing
 An improper specimen-collection technique
 Urine in the catheter or drainage tube being allowed to re-enter bladder (reflux)
 Improper hand hygiene

Respiratory Tract

Contaminated respiratory therapy equipment
 Failure to use aseptic technique while suctioning airway
 Improper disposal of secretions
 Improper hand hygiene

Bloodstream

Contamination of intravenous fluids by tubing or needle changes
 The insertion of drug additives to intravenous fluid
 The addition of a connecting tube or stopcocks to an intravenous system
 Improper care of a needle-insertion site
 Improper insertion technique
 Contaminated needles or catheters
 Failure to change the intravenous access site when inflammation first appears
 Improper technique during the administration of multiple blood products
 Improper care of peritoneal or hemodialysis catheters
 Improper handwashing and hand hygiene

* BOX 32-4

FOCUS ON OLDER ADULTS

- An age-related decline in immune system function, termed *immune senescence*, increases the body's susceptibility to infection and lessens the strength of the overall immune response (Freid, 2009).
- Age-related changes alter the response to infection resulting in atypical signs and symptoms.
- Chronic disease, prevalent among older adults, allows infectious agents to readily invade; hospitalization and institutionalization as a result of chronic disease also increase older adults' exposure to pathogens (Freid, 2009).
- Risks associated with the development of infections in older patients include poor nutrition, unintentional weight loss, and low serum albumin levels (Wells & Dumbrell, 2006).
- Age-related changes in immunity contribute to the increased risk for acquiring pneumonia and influenza in older adulthood, both of which have significant age-related increases in mortality rates (Freid, 2009).
- Older adults present with an altered response to infection with atypical signs and symptoms such as confusion.

Data from Freid, L. P. (2009). Epidemiology of aging: Implications of the aging society. In Goldman, L., & Ausiello, D. (Eds.), *Cecil essentials of medicine* (23rd ed., pp. 112–136). Philadelphia, PA: Lippincott; Saunders.

Nursing Process in Infection Control

◆ Assessment

When considering infection prevention, you must assess a patient's defence mechanisms, susceptibility, and knowledge of infections. A review of disease history with the patient and family may reveal an exposure to a communicable disease. A thorough review of the patient's clinical condition may allow you to detect signs and symptoms of an infection or a risk for infection. Information about the patient's defences against infection can be determined by an analysis of laboratory findings. By knowing the factors that increase susceptibility or risk for infection, you are better able to plan preventive therapy that includes aseptic techniques. Recognizing early signs and symptoms of infection allows you to alert others on the health care team to the potential need for therapy and to initiate supportive nursing measures.

because of the effects of the aging process itself (Box 32-4). Extended stays in health care institutions, increased disability, and prolonged recovery times are all potential outcomes of HAIs. HAIs decrease the patient's quality of life and increase costs to the health care system. Therefore, their prevention is an important part of managed care.

► BOX 32-5 Risk Factors for Infection

Inadequate Primary Defences

- Broken skin or mucosa
- Traumatized tissue
- Decreased ciliary action
- Obstructed urine outflow
- Altered peristalsis
- A change in the pH of secretions
- Decreased mobility

Inadequate Secondary Defences

- A reduced hemoglobin level
- The suppression of WBCs (drug or disease related)
- A suppressed inflammatory response (drug or disease related)
- A low WBC count (leukopenia)

Status of Defence Mechanisms

You can determine the status of the patient's normal defence mechanisms against infection through a review of the physical assessment findings and the patient's medical condition. For example, any break in the skin or mucosa is a potential site for infection. Similarly, a chronic smoker is at greater risk for acquiring a respiratory tract infection after general surgery because the cilia of the lung are less likely to propel retained mucus from the lung's airways. Any reduction in the body's primary or secondary defences against infection places a patient at risk (Box 32-5).

Patient Susceptibility

Many factors influence susceptibility to infection. You will gather information about each factor through the patient's and family's history.

Age. Throughout the lifespan, susceptibility to infection changes. An infant has immature defences against infection. Born with only the antibodies provided by the mother, the infant's immune system is incapable of producing the necessary immunoglobulins and WBCs to adequately fight some infections. However, breastfed infants have greater immunity than do bottle-fed infants because they receive the mother's antibodies through the breast milk. As the child grows, the immune system matures; however, the child is still susceptible to organisms that cause the common cold, intestinal infections, and, if the child is not vaccinated, infectious diseases such as mumps and measles.

The young or middle-aged adult has refined defences against infection. Normal flora, body system defences, inflammation, and the immune response provide protection against invading microorganisms. Viruses are the most common cause of infectious illness in young and middle-aged adults.

Defences against infection change with aging (Freid, 2009). The immune response, particularly cell-mediated immunity, declines. Older adults also undergo alterations in the structure and function of the skin, urinary tract, and lungs. For example, the skin loses its turgor and the epithelium thins; as a result, the skin is more easily abraded or torn. This increases the potential for invasion by pathogens (Table 32-4).

Nutritional Status. When protein intake is inadequate as a result of poor diet or debilitating disease, the rate of protein breakdown exceeds that of tissue synthesis (see Chapter 42). A reduction in the intake of protein and other

nutrients such as carbohydrates and fats reduces the body's defences against infection and impairs wound healing (see Chapter 42). Patients with illnesses or problems that increase protein requirements are at further risk. These problems include traumatic injury, extensive burns, and conditions causing fever. Patients who have had surgery also require increased protein.

You need to assess patients' dietary intake and ability to tolerate solid foods. Patients who have difficulty with swallowing, who experience alterations in digestion, or who are too confused or weak to feed themselves are at risk for inadequate dietary intake. A dietitian may be called in to assess the nutritional adequacy of a patient's diet. When preparing a patient for discharge, you should evaluate the patient's and family's understanding of nutritional needs.

Stress. The general adaptation syndrome is the body's response to emotional or physical stress (see Chapter 29). During the alarm stage, the basal metabolic rate increases as the body uses energy stores. Adrenocorticotrophic hormone acts to increase serum glucose levels and decrease unnecessary anti-inflammatory responses through the release of cortisone. If stress continues or becomes intense, elevated cortisone levels result in a decreased resistance to infection. Continued stress leads to exhaustion, wherein energy stores are depleted and the body has no resistance to invading organisms. The same conditions that increase nutritional requirements, such as surgery or trauma, also increase physiological stress.

Disease Process. Patients with diseases of the immune system are at particular risk for infection. Leukemia, AIDS, lymphoma, and aplastic anemia are conditions that compromise a host by weakening defences against infectious organisms. Patients with leukemia, for example, are unable to produce normal WBCs to effectively ward off infection.

Patients with chronic diseases such as diabetes mellitus and multiple sclerosis are also more susceptible to infection because of general debilitation and nutritional impairment. Cancer (which alters the immune response), peripheral vascular disease (which reduces blood flow to injured tissues), and diseases that impair body system defences, such as emphysema and bronchitis (which impair ciliary action and thicken mucus), increase susceptibility to infection. Patients with burns have a very high susceptibility to infection because of the damage to skin surfaces. The greater the depth and extent of the burns, the higher the risk for infection.

Medical Therapy. Some drugs and medical therapies compromise immunity to infection. You will need to assess your patients' history to determine whether they take medications at home that increase infection susceptibility. A review of therapies received within the health care setting may further reveal risks. Adrenal corticosteroids, prescribed for several conditions, are anti-inflammatory drugs that cause protein breakdown and impair the inflammatory response against bacteria and other pathogens. Cytotoxic or antineoplastic drugs attack cancer cells but cause side effects such as depression of bone marrow activity and normal cell toxicity. When bone marrow activity is depressed, the body is unable to produce lymphocytes and sufficient WBCs. When normal cells become altered by antineoplastic agents, cellular defences against infection fail. Cyclosporine and other immunosuppressant drugs, which decrease the body's immune response, are commonly taken by organ transplant recipients. The immunosuppressants prevent organ and tissue rejection, but they also increase the recipients' susceptibility to infection.

► **TABLE 32-4** Assessing the Risk of Infection in Older Adults

Component	Possible Changes With Age	Possible Outcomes
Skin	Thinner dermal and epidermal layers, decreased collagen strength, decreased skin elasticity, decreased sweating	Pressure ulcers
Peripheral nerves	Reduced sensitivity, particularly in patients with a history of alcohol abuse, vitamin B ₁₂ deficiency, and diabetes mellitus	Pressure ulcers, patients unaware of trauma to skin, leading to infection
Circulation	Heart failure, calcified mitral and aortic valves	Pneumonia, bacterial endocarditis
Peripheral circulation	Loss of elasticity of veins (prone to distension), less effective venous valves, blood pooling in lower extremities	Venous stasis ulcers
Mouth	Dehydration, reduction in saliva production, functional inability to maintain oral hygiene	Parotid gland infection, periodontal disease, localized abscess, bacteremia (i.e., bacteria in the blood)
Gastrointestinal tract	Loss of ability to secrete stomach acid in 30% of persons older than 70 years	<i>Salmonella</i> diarrhea
Pulmonary system	Increased colonization of oropharynx, impaired mucociliary clearance, decreased macrophage function, decreased cough reflex	Viral and bacterial pneumonia
Genitourinary tract	Prostatic hypertrophy or hyperplasia, urethral strictures, age-related hormonal changes in vaginal wall, pelvic floor relaxation, ureterocele or cystocele, degeneration of nerves leading to neurogenic bladder, use of tricyclic antidepressants result in urinary retention, dehydration	Asymptomatic bacteriuria (i.e., bacteria in the urine), cystitis, pyelonephritis
Nutrition	Malnutrition, vitamin deficiency (vitamin A, vitamin C, pyridoxine, and riboflavin), protein and caloric deficiencies	Impaired immune response to infection
Drug therapy	Corticosteroid and cytotoxic drugs	Impaired immune response to infection in patients already at risk for decline in immune system function
Long-term care residency	Surveys indicate as many as 15% of residents living in long-term care facilities have an infection at any one time. The elderly population and the health care setting may provide a setting that promotes the development and spread of infections. Preventive measures should be instituted such as increased hand hygiene, reduced use of indwelling catheters, increased efforts to reduce aspiration, increased administration of vaccines, and prudent use of antibiotics	Frequent serious infection, increased risk of pneumonia and urinary tract infections. Increased risk of acquiring a multidrug-resistant organism

Reference: Carrico, R. (Ed.). (2009). *APIC text of infection control and epidemiology* (3rd edition, pp. 401–406). Washington, DC: Association for Professionals in Infection Control and Epidemiology (APIC).

Patients with cancer who are receiving radiotherapy are at risk for infection. The massive doses of radiation that destroy cancerous cells can also depress bone marrow activity and destroy normal cells.

Clinical Appearance

The signs and symptoms of infection may be local or systemic. Localized infections are most common in areas of skin or mucous membrane breakdown, such as surgical and traumatic wounds, pressure ulcers, and mouth lesions. Infections also develop locally in cavities beneath the skin; an example is an abscess.

To assess an area for localized infection, you should first inspect the area for redness and swelling caused by inflammation. Because drainage from open lesions or wounds may occur, you must wear disposable gloves. Infected drainage may be yellow, green, or brown, depending on the pathogen. Ask the patient about pain or tenderness around the site. The patient may complain of tightness and pain caused by edema. If the infected area is large enough, movement of a body part may be restricted. Gentle palpation of an infected area usually results in some degree of tenderness.

Systemic infections cause more generalized symptoms than do local infections. Systemic infections usually result in fever, fatigue, and malaise. Lymph nodes that drain the area of

infection often become enlarged, swollen, and tender during palpation. For example, an abscess in the peritoneal cavity may cause the enlargement of the lymph nodes in the groin. An infection of the upper respiratory tract may cause cervical lymph node enlargement. If an infection is serious and widespread, all major lymph nodes may enlarge. Systemic infections commonly cause a loss of appetite, nausea, and vomiting.

Systemic infections may develop after treatment for a localized infection has failed. You should be alert for changes in a patient's level of activity and responsiveness. As systemic infections develop, the patient may become lethargic and complain of a loss of energy. An elevation in body temperature may lead to episodes of increased heart and respiratory rates and low blood pressure. The involvement of major body systems may produce specific signs. For example, a pulmonary infection may result in a productive cough with purulent sputum. A urinary tract infection may result in cloudy, foul-smelling urine.

In older adults, infection may not present with typical signs and symptoms. Fever, pain, and swelling are often absent in older adults because they tend to have lower body temperatures, decreased pain sensation, and less immune response to infection. As a result, in older adults, infection is often advanced before it is identified. Atypical symptoms such as a change in

behaviour (e.g., new or increased confusion, incontinence, or agitation) may be the only symptoms of an infectious illness (Freid, 2009). For example, as many as 20% of older adults with pneumonia do not have the typical signs and symptoms of fever, shaking, chills, and “rusty” productive sputum. The only symptoms present may be an increased heart rate with no apparent reason, confusion, or generalized fatigue.

Laboratory Data

A review of laboratory test results may confirm infection (Table 32-5). However, laboratory values alone are not sufficient to detect infection; other clinical signs must be assessed. Factors other than infection may alter test values. For example, trauma and physical stress can cause an elevation in the number of neutrophils. A culture may show the growth of an organism in the absence of overt signs of infection.

Patients With Infection

A patient with infection may have a variety of health problems. You need to assess ways that the infection affects the patient’s and family’s needs—these may be physical, psychological, social, or economic. For example, a patient with a chronic

disease such as AIDS may experience serious psychological problems as a result of self-imposed isolation or rejection by family and friends. Using a case-management approach, you can determine the patient’s and family’s ability to adjust to the disease and the resources available to help them manage health care challenges (Cheever, 2007).

❖ Nursing Diagnosis

During assessment, you gather objective findings, such as an open incision or a reduced caloric intake, and subjective data, such as a patient’s complaint of tenderness over a surgical wound site (Box 32-6). You then interpret the data carefully, looking for clusters of defining characteristics or risk factors that create a pattern suggesting a specific nursing diagnosis. The following are examples of nursing diagnoses that may apply:

- *Disturbed body image*
- *Risk for infection*
- *Risk for injury*
- *Imbalanced nutrition—less than body requirements*
- *Impaired oral mucous membrane*

► **TABLE 32-5** Laboratory Tests to Screen for Infection

Laboratory Value	Normal (Adult) Values	Indication of Infection
White blood cell (WBC) count	5–10 × 10 ⁹ /L	Increased in acute infection, neoplasm, allergy, neoplasm, or immunosuppression, decreased in certain viral or overwhelming infections
Erythrocyte sedimentation rate (ESR) Westergren method	Up to 15 mm/hour for men and 20 mm/hour for women	Elevated in presence of inflammatory process, acute and chronic infection, tissue necrosis or infarction
Iron level	8–25 mcml/L	Decreased in chronic infection
C-reactive protein	<10 mg/L	An acute phase reactant protein that is elevated in the presence of an acute inflammatory process
Cultures of urine and blood	Normally sterile, without microorganism growth	Presence of infectious microorganism growth
Cultures and Gram stain of wound, sputum, and throat	No WBCs on Gram stain, possible normal flora	Presence of infectious microorganism growth and WBCs on Gram stain
WBC	Differential Count (Percentage of Each Type of WBC)	Indication of Infection
Neutrophils	55%–70%	Increased in acute suppurative infection, decreased in overwhelming bacterial infection (older adult)
Lymphocytes	20%–40%	Increased in chronic bacterial and viral infection, decreased in sepsis
Monocytes	2%–8%	Increased in protozoal, rickettsial, and tuberculosis infections
Eosinophils	1%–4%	Increased in parasitic infection
Basophils	0.5%–1%	Normal during infection

Data from Pagana, K. D., & Pagana, T. J. (2010). *Mosby’s manual of diagnostics and laboratory tests* (4th ed.) St Louis, MO: Mosby/Elsevier.

► BOX 32-6 NURSING DIAGNOSTIC PROCESS

Assessment Activities	Defining Characteristics	Nursing Diagnosis
Check results of laboratory tests.	WBC count 3.9 × 10 ⁹ /L	<i>Risk for infection related to neutropenia.</i>
Review current medications.	Patient receiving azathioprine (Imuran), an immunosuppressant	
Identify potential sites of infection.	Intravenous catheter in right forearm in place for 3 days Foley catheter draining amber-coloured urine	

- Risk for impaired skin integrity
- Social isolation
- Impaired tissue integrity

It may be necessary for you to validate data (e.g., by inspecting the integrity of a wound more carefully). Likewise, additional data such as laboratory findings may be helpful. The proper selection of appropriate nursing diagnoses depends on the correct analysis and organization of data.

The diagnosis must have the correct etiological factor for you to establish an appropriate and well-thought-out plan. For example, minimizing the risk for infection related to broken skin requires good hygiene measures and wound care; minimizing the risk for infection related to malnutrition requires good nutritional support and fluid balance.

You may diagnose a risk for infection or make diagnoses that result from the effects of infection on the patient's health status. Your success in planning appropriate nursing interventions depends on the accuracy of the diagnosis and your ability to meet the patient's needs.

❖ Planning

Goals and Outcomes

The patient's care plan is based on each nursing diagnosis and related factors (Box 32-7). You develop a plan that sets attainable outcomes so that interventions are purposeful and directed. If you are caring for a patient with the nursing diagnosis *risk for infection related to broken skin*, you must implement skin and wound care measures to promote healing. The expected outcomes "reduction in wound size by 1 cm" and "absence of drainage" represent targets for measuring the patient's improvement. Once outcomes are met, the goal of "skin intact and without drainage" can be reached. Interventions are selected in collaboration with the patient, the family, and others on the health care team. You direct the care in the acute care setting; care may also involve other professionals in assisting with instructions on post-discharge procedures. Common goals of care relating to infection include the following:

► BOX 32-7 NURSING CARE PLAN

Risk for Infection

Assessment

Mrs. Spicer was admitted to the medical nursing unit three days ago with a diagnosis of lymphoma. She received her first dose of multiagent chemotherapy yesterday. Jess Ralston is the student nurse caring for Mrs. Spicer. He begins his shift by conducting a focused assessment.

Assessment Activities

Review patient's chart for laboratory data reflecting immune function.

Findings and Defining Characteristics

Data show a reduction in number of WBCs (leukopenia).

Ask patient to describe appetite and review food intake for past 24 hours. Weigh patient. Measure height.

Mrs. Spicer reports she has not had an interest in eating for a couple of weeks. She has lost approximately 2.5 kg. Her current weight is 57 kg, and her height is 170 cm. Her food intake yesterday consisted of a small cup of applesauce, a half bowl of soup, some crackers, and two glasses of juice. Mrs. Spicer states, "I get full easily and lose interest in food."

Palpate patient's cervical and clavicular lymph nodes.

Lymph nodes are enlarged and painless.

Review effects of chemotherapy in drug reference.

Multiagent chemotherapy causes drug-induced pancytopenia.

Nursing Diagnosis: Risk for infection related to immunosuppression and reduced food intake.

Planning

Goals (Nursing Outcomes Classification)*

Patient will remain free of infection.

Expected Outcomes

Risk Detection

Patient will remain afebrile.

Patient will develop no signs or symptoms of local infection (e.g., will remain free of cough, cloudy or foul-smelling urine, and purulent drainage from open wound or normal body opening).

Patient will become knowledgeable of infection risks.

Knowledge: Infection Control

Patient will identify routines to follow in the home that reduce the transmission of microorganisms.

Patient will identify signs and symptoms indicating infection to report to her health care provider.

*Outcome classification labels from Moorhead, S., Johnson, M., Maas, M. L. & Swanson, E. (Eds.). (2008). *Nursing outcomes classification (NOC)* (4th ed.). St Louis, MO: Mosby.

► BOX 32-7 NURSING CARE PLAN—cont'd

Interventions (Nursing Intervention Classification)[†]

Prevention and Early Detection

Monitor patient's body temperature routinely, inspect oral cavity for lesions, inspect urethral and vaginal orifices for drainage or discharge, inspect intravenous access site for drainage, and observe patient for evidence of cough.

Rationale

Interventions are designed to prevent and ensure early detection of infection in a patient at risk (Bulechek et al., 2008).

Practise hand hygiene routinely before caring for a patient, between patients, and before any invasive procedures.

Rigorous hand hygiene reduces bacterial counts on the hands (Health Canada, 2007).

Teach patient how to perform hand hygiene correctly.

Patient can easily come in contact with infectious agents that can cause infection.

Consult with dietitian about providing a high-calorie, high-protein, low-bacteria diet. Minimize the intake of salads, undercooked meat, pepper, paprika, and raw fruits and vegetables. Offer small, frequent meals.

Maintaining calorie and protein intake will prevent weight loss. Foods high in bacteria should be avoided because they increase the risk for gastrointestinal infection (Ignatavicius & Workman, 2002).

Infection Control

Instruct patient to report the following to the physician: temperature $>38^{\circ}\text{C}$, persistent cough with or without sputum, pus or foul-smelling drainage from the body site, the presence of an abscess, urine that is cloudy or foul smelling, or burning on urination.

Signs and symptoms are indicative of local or systemic infection.

Teach patient to follow these activities at home:

- Avoid crowds and large gatherings of persons.
- Bathe daily.
- Do not share personal hygiene items with family members (e.g., toothbrush, washcloth, and deodorant stick).
- Take your temperature twice daily.
- Do not drink water that has been standing for >15 minutes.
- Do not reuse cups or glasses without washing.

These measures are designed to prevent infection in patients with impaired immune function (Ignatavicius & Workman, 2002).

[†]Intervention classification labels from Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St Louis, MO: Mosby.

Evaluation

Nursing Actions

Compare patient's body temperature and other physical findings with baseline data.

Patient Response and Finding

Mrs. Spicer remains afebrile and denies having cough or burning on urination. No signs of drainage or discharge from body site are evident.

Achievement of Outcome

Mrs. Spicer has no active infection at this time.

Ask patient to describe signs and symptoms to report to health care provider.

Mrs. Spicer is able to identify the temperature range to report. She is able to describe cough. She is unable to identify signs of urinary infection or local discharge.

Mrs. Spicer has a partial understanding of signs and symptoms to report. I will require additional instruction and information sheet.

Ask patient to explain the measures to take at home to reduce exposure to infectious agents.

Mrs. Spicer is able to discuss need to avoid sharing personal hygiene articles. She has asked for a list of other precautions and requested that her husband be included in discussion.

Mrs. Spicer has a partial understanding of restrictions. I will obtain printed guidelines and include her husband in discussion this evening.

- Preventing exposure to infectious organisms
- Controlling or reducing the extent of the infection
- Maintaining resistance to infection
- Educating the patient and family about infection control techniques

Setting Priorities

In collaboration with the patient, you establish priorities for the goals of care. For example, for a patient who has an open wound and cancer and cannot tolerate solid foods, the priority of administering therapies that promote wound healing

exceeds the goal of educating the patient to assume self-care therapies at home. When the patient's condition improves, the priorities will change, and patient education will become an essential intervention.

Continuity of Care

The development of a care plan includes infection prevention practices. You may initiate appropriate referrals, such as to a dietitian, infection control professional, or home care nurse, to collaborate in a patient's care. When care is being administered in the home, you should ensure that the environment supports

good infection control practices. For example, if a patient does not have running water, you need to bring a waterless antimicrobial solution during visits to ensure adequate handwashing and hand hygiene. Educating patients and families is also an important aspect of prevention.

❖ Implementation

By recognizing and assessing a patient's risk factors and implementing appropriate measures, you can reduce the risk of infection.

Health Promotion

You may prevent an infection from developing or spreading by minimizing the numbers and kinds of organisms transmitted to potential infection sites. Eliminating reservoirs of infection, controlling portals of exit and entry, and avoiding actions that transmit microorganisms prevent pathogens from finding a new site in which to grow. The proper use of sterile supplies, barrier protection, and proper handwashing and hand hygiene are examples of methods that nurses use to control the spread of microorganisms. A further preventive measure is to strengthen a potential host's defences against infection. Nutritional support, rest, maintenance of physiological protective mechanisms, and receipt of recommended immunizations (Box 32-8) protect a patient from invasion by pathogens.

Being vigilant about infection control helps you to apply good medical–surgical aseptic practices at the right time and in the right clinical situation. When a patient develops an

infection, you need to continue preventive care so that health care personnel and other patients are not exposed to the infection. Isolation precautions may be necessary for patients with communicable diseases; the environment is controlled by barriers against the transmission of infection (see Isolation Guidelines section).

Acute Care Measures

Treatment of an infectious process includes eliminating the infectious organisms and supporting the patient's defences. To identify the causative organism, you may collect specimens of body fluids or drainage from infected body sites for cultures. When the disease process or causative organism has been identified, the physician prescribes the treatment that is most effective for the situation. You properly administer antibiotics and other treatments, watch for adverse reactions, and assess the progress of the infection.

Systemic infections necessitate measures to prevent complications of fever (see Chapter 30). Maintaining the patient's intake of fluids prevents dehydration resulting from diaphoresis. Because of the patient's increased metabolic rate, adequate nutritional intake must be ensured. Rest preserves energy for the healing process.

Localized infections often necessitate measures to remove debris to promote healing. You will need to apply the principles of wound care to remove any infected drainage from the wound site and support the integrity of healing wounds. Special dressings can be applied to facilitate the removal of infectious drainage and promote healing of wound margins. Drainage tubes may be inserted to remove infected drainage from body cavities. You must use medical and surgical aseptic techniques to manage wounds and ensure correct handling of all drainage or body fluids (see Chapter 46).

During the course of infection, you can support the patient's body defence mechanisms. For example, if a patient has infectious diarrhea, you must maintain skin integrity to prevent breakdown and the entrance of microorganisms. Other routine hygiene measures such as bathing and oral care protect the skin and mucous membranes from invasion and overgrowth of microorganisms.

Asepsis

Your efforts to minimize the onset and spread of infection are based on the principles of aseptic technique. **Asepsis** is the absence of pathogenic (disease-producing) microorganisms. *Aseptic technique* refers to practices that keep a patient as free from pathogens as possible. The two types of aseptic technique are medical asepsis and surgical asepsis.

Medical asepsis, or clean technique, includes procedures used to reduce and prevent the spread of microorganisms. Hand hygiene, using clean gloves (i.e., disposable gloves) to prevent direct contact with blood or body fluids, and cleaning the environment routinely are examples of medical asepsis. The principles of medical asepsis are commonly followed in the home, as in washing hands before preparing food.

After an object becomes unsterile or unclean, it is considered *contaminated*. In medical asepsis, an area or object is considered contaminated if it contains or is suspected of containing pathogens. For example, a used bedpan, the floor, and a used dressing are contaminated.

You need to follow certain principles and procedures, including routine practices, to prevent infection and control its spread (see Isolation Guidelines section). During your daily

BOX 32-8

FOCUS ON PRIMARY HEALTH CARE

Immunizations

Immunizations are an essential component of disease prevention. You should encourage proper immunization of infants, children, those at risk, and older adults. In Canada, most provinces provide free-of-charge immunization to infants against measles, mumps, rubella, diphtheria, tetanus, acellular pertussis, and poliomyelitis. Parents may be required to pay to have their infant or child vaccinated against *Haemophilus influenzae* type b (Hib), human papillomavirus (HPV), varicella, and hepatitis B. The HPV vaccine is available in Canada for female patients 9 to 26 years of age. For maximum benefit, it should be given before the patient becomes sexually active.

Older adults and those who have underlying medical conditions are at risk for influenza and pneumonia and are therefore offered influenza vaccines each year and pneumococcal vaccines as per the recommended schedule, which varies according to the recipient's age. You should remind patients of the importance of having a tetanus–diphtheria booster vaccination every 10 years. Health care workers who care for persons at high risk for complications from influenza should be immunized for influenza yearly as well.

In most provinces and territories, public health nurses or community nurses hold free immunization clinics for patients at risk during an outbreak of a potentially deadly infection such as bacterial meningitis.

Source: Health Canada. (2006). *Canadian immunization guide* (7th ed.). Ottawa: Public Health Agency of Canada. Retrieved from http://www.phac-aspc.gc.ca/publicat/cig-gci/pdf/cig-gci-2006_e.pdf.

routine care, use basic medical aseptic techniques to break the infection chain. Because infections are readily transmitted between patients and caregivers, it may become necessary for you to follow isolation precautions as appropriate (see Isolation Guide lines section).

You are responsible for providing the patient with a safe environment. The effectiveness of infection control practices depends on your and your colleagues' conscientiousness and consistency in using effective aseptic technique. It is easy to forget key procedural steps or, in a hurry, to take shortcuts that break aseptic procedures. However, your failure to be meticulous places the patient at risk for an infection that can seriously impair recovery or lead to death.

Control or Elimination of Infectious Agents. Proper cleaning, disinfection, and sterilization of contaminated objects significantly reduce and often eliminate microorganisms. In health care centres, a sterile processing department disinfects and sterilizes reusable supplies. However, you also may be required to perform these functions. Many principles of cleaning and disinfection also apply to the home.

Cleaning. Cleaning is the physical removal of foreign material (e.g., dust, soil, and organic material such as blood, secretions, excretions, and microorganisms) from objects and surfaces (CDC, 2008; Health Canada, 2007). In general, cleaning involves the use of water and mechanical action with detergents or enzymatic products. When an object comes in contact with infectious or potentially infectious material, the object is contaminated. Reusable objects must be cleaned thoroughly before reuse and then either disinfected or sterilized according to the manufacturer's recommendations.

When cleaning equipment that is soiled by organic material such as blood, fecal matter, mucus, or pus, you should take appropriate measures to protect yourself against contamination. These may include wearing a mask and protective eyewear (or a face shield) and waterproof gloves. These barriers provide protection from infectious organisms. A brush and detergent or soap are needed for cleaning.

The following steps ensure that an object is clean:

1. Rinse a contaminated object or article with cold running water to remove organic material. Hot water causes the protein in organic material to coagulate and stick to objects, making removal difficult.
2. After rinsing, wash the object with soap and warm water. Soap or detergent reduces the surface tension of water and emulsifies the dirt or remaining material. Rinse the object thoroughly to remove the emulsified dirt.
3. Use a brush to remove dirt or material in grooves or seams. Friction dislodges the contaminated material for easy removal. Open any hinged items for cleaning.
4. Rinse the object in warm water.
5. Dry the object and prepare it for disinfection or sterilization if indicated by the intended use of the item.
6. The brush, gloves, and sink in which the equipment is cleaned should be considered contaminated and should be cleaned and dried.

Disinfection and Sterilization. Disinfection is the elimination of all pathogens except bacterial spores (CDC, 2008). Disinfectants are used on inanimate objects; antiseptics are used on living tissue. Disinfection usually involves chemicals, heat, or ultraviolet light. An item must be thoroughly cleaned before it is disinfected. Examples of disinfectants are alcohols, chlorines, glutaraldehydes, phenols, and quaternary ammonium compounds. These chemicals can be caustic and

► BOX 32-9

Categories for Sterilization, Disinfection, and Cleaning

Critical Items

Critical items are instruments and devices that enter sterile tissue or the vascular system. They present a high risk of infection if the items are contaminated with microorganisms, including bacterial spores. Critical items must be thoroughly cleaned and sterilized. Examples of these items follow:

- Surgical instruments
- Intravascular catheters
- Urinary catheters
- Needles

Semicritical Items

Semicritical items are devices that come in contact with mucous membranes or nonintact skin but do not penetrate them. These items also present a risk of infection and must be free of all microorganisms (except bacterial spores). Semicritical items must be thoroughly cleaned and disinfected.

The following are examples of these items:

- Electronic thermometers
- Respiratory therapy equipment
- Endotracheal tubes
- Gastrointestinal endoscopes
- Vaginal and nasal specula

Noncritical Items

Noncritical items are items that either touch only intact skin but not mucous membranes or do not directly touch the patient. Noncritical items must be cleaned or cleaned and disinfected. Examples of these items follow:

- Bedpans, urinals, and commodes
- Blood pressure cuffs
- Linens
- Stethoscopes
- Some eating utensils

toxic to tissues. Some disinfectants are indicated for use only on noncritical items; you should read the label and follow the manufacturer's recommendations for use.

Sterilization is the destruction of all microorganisms, including spores. Steam under pressure, ethylene oxide gas, hydrogen peroxide plasma, and chemicals are the most common sterilizing agents. Items must be cleaned thoroughly before they can be sterilized.

Whether an item is to be simply cleaned, or cleaned and disinfected or sterilized, depends on the intended use of the item. Devices are classified in three categories (Box 32-9). You should be familiar with your agency's policy and procedures for cleaning, handling, and delivering care items for eventual disinfection and sterilization. Workers especially trained in disinfection and sterilization should perform most of the procedures. Efficacy of the disinfecting or sterilizing method is influenced by the following factors:

- *Concentration of solution and duration of contact.* A weakened concentration or shortened exposure time may lessen effectiveness.
- *Type and number of pathogens.* Certain organisms are killed more easily than others by disruption. Higher numbers of pathogens on an object necessitate longer disinfecting time.

► TABLE 32-6

Examples of Disinfection and Sterilization Processes**Characteristics****Moist Heat**

Steam is moist heat under pressure. When exposed to high pressure, water vapour can attain a temperature above boiling point to kill pathogens and spores.

Examples of Use

An autoclave is used to sterilize surgical instruments and dressings.

Chemicals

A number of chemical disinfectants are used in health care, including alcohols, chlorines, formaldehyde, glutaraldehydes, hydrogen peroxide, iodophors, phenolics, and quaternary ammonium compounds. Each product performs in a unique manner and is used for a specific purpose.

Chemicals are used for the disinfection of instruments and equipment such as thermometers and endoscopes. Use the appropriate facility-approved disinfectant in a safe manner (e.g., with gloves, proper ventilation) for the approved purpose.

Ethylene Oxide Gas

Ethylene oxide gas destroys spores and microorganisms by altering cells' metabolic processes. Fumes are released within an autoclave-like chamber. This gas is toxic to humans, and aeration time varies with products.

This gas sterilizes some rubber and plastic items.

Boiling Water

Boiling is the least expensive method of sterilization for use in the home. Bacterial spores and some viruses resist boiling. It is not used in hospitals.

The items (e.g., glass baby bottles) should be boiled for at least 15 minutes.

- **Surface areas to treat.** All dirty surfaces and areas must be fully exposed to disinfecting and sterilizing agents.
- **Temperature of the environment.** Disinfectants tend to work best at room temperature.
- **Presence of soap.** Soap may cause certain disinfectants to be ineffective. Thorough rinsing of an object is necessary before disinfecting.
- **Presence of organic materials.** Disinfectants can become inactivated unless blood, saliva, pus, or body excretions are already washed off.

Table 32-6 lists processes for disinfection and sterilization and their characteristics. Selection of the method for disinfecting or sterilizing an item depends on the intended use and nature of the item (e.g., some delicate instruments cannot tolerate steam and must be sterilized with gas or plasma).

Control or Elimination of Reservoirs. To control or eliminate reservoir sites for infection, you need to eliminate or control sources of body fluids, drainage, or solutions that

► BOX 32-10

Infection Control to Reduce Reservoir Sites**Bathing**

Use soap and water to remove drainage, dried secretions, or excess perspiration.

Dressing Changes

Change dressings that become wet or soiled (see Chapter 46).

Contaminated Articles

Place tissues, soiled dressings, and soiled linen in moisture-resistant bags for proper disposal.

Contaminated Needles

Engage the safety features of all sharp devices and dispose of them in a puncture-proof container. Place syringes, uncapped hypodermic needles, and intravenous needles in puncture-proof containers, which should be located in patient rooms or treatment areas so that exposed, contaminated equipment need not be carried a distance (see Chapter 33). *Do not recap needles or attempt to break them.*

Bedside Unit

Keep table surfaces clean and dry.

Bottled Solutions

Do not leave bottled solutions open for prolonged periods. Keep solutions tightly capped. Date bottles when opened and discard according to your facility's policy.

Surgical Wounds

Keep drainage tubes and collection bags patent to prevent the accumulation of serous fluid under the skin surface.

Drainage Bottles and Bags

Empty and dispose of drainage suction bottles according to your health agency's policy. Empty all drainage systems on each shift unless otherwise ordered by a physician. Never raise a drainage system (e.g., urinary drainage bag) above the level of the site being drained unless the drainage system is clamped off.

might harbour microorganisms. You must also carefully discard articles that become contaminated with infectious material (Box 32-10). All health care institutions must have guidelines for the disposal of infectious waste according to provincial or territorial laws.

Control of Portals of Exit. You will need to follow several measures to minimize or prevent infectious organisms from exiting the body. To control organisms exiting via the respiratory tract, you should wear a mask as needed, avoid talking directly into patients' faces, and never talk, sneeze, or cough directly over surgical wounds or sterile dressing fields. You should cover your mouth or nose when sneezing or coughing. You are also responsible for teaching patients to protect others when they sneeze or cough and for providing patients with disposable wipes or tissues to control the spread of microorganisms.

If you have an upper respiratory tract infection, you should consider not working; you may be required to remain at home. If you continue to work with patients, you should wear a mask when working closely with a patient and pay special attention to hand hygiene. You should not be caring for patients who are highly susceptible to infection (e.g., an immunosuppressed patient or a neonate).

Another way of controlling the exit of microorganisms is through the careful handling of blood, body fluids, secretions, or excretions (e.g., urine, feces, vomitus, and exudate). Contaminated fluids can easily splash while being discarded or cleaned up. You should always wear disposable gloves when handling blood, body fluids, secretions, or excretions. Masks, gowns, and protective eyewear should be worn if splashing or contact with any fluids is possible. You should appropriately dispose of disposable soiled items in impervious plastic bags. Laboratory specimens from all patients are handled as if they were infectious.

Control of Transmission. Effective control of infection requires you to remain aware of the modes of transmission and ways to control them. In the hospital, home, or long-term care facility, a patient should have a personal set of care items. The sharing of bedpans, urinals, bath basins, and eating utensils can easily lead to transmission of infection. Thermometers, even when individually used, warrant special care. Because the patient's own mucus can become a source of microorganism growth, the electronic thermometer is used with a disposable sheath over the probe; the sheath is discarded after each use. Single-use chemical strip thermometers present less risk of infection than do other thermometers. Use of electronic thermometers for rectal temperatures has been associated with nosocomial diarrhea (Jernigan et al., 1998). The organism *C. difficile* is able to survive on inanimate surfaces such as a thermometer probe for weeks to months. In institutions where nosocomial diarrhea occurs, electronic thermometers are not recommended for rectal temperatures.

To prevent transmission of microorganisms through indirect contact, soiled items and equipment must not touch your clothing. A common error is to carry dirty linen in the arms against the uniform. Fluid-resistant linen bags should be used, or soiled linen should be carried with hands held out from the body. Laundry hampers should be replaced before they are overflowing.

Handwashing/Hand Hygiene. Hand hygiene is the most important and most basic technique in preventing the transmission of infections. Hand hygiene includes using an instant alcohol hand antiseptic before and after providing patient care, handwashing with soap and water when hands are visibly soiled, and performing a surgical scrub when necessary. The components of good **handwashing** include using an adequate amount of soap, rubbing the hands together to lather the soap and create friction, and rinsing under a stream of water (Health Canada, 2007). The purpose is to remove soil and transient organisms from the hands and to reduce total microbial counts over time.

Contaminated hands are a prime cause of cross-infection. For example, imagine you are caring for a patient who has excessive pulmonary secretions, and you assist the patient in expectorating mucus and disposing of the tissues in a bedside container. The patient's roommate asks you to open containers of food on the meal tray. You then leave the patient's room to pour a dose of medication that is to be taken in five minutes. If you fail to perform hand hygiene before opening the containers of food or pouring the medication, organisms from the first patient's mucus can easily be transmitted to the roommate's food and to the medication container. Decreased nosocomial infection rates have been reported with improved handwashing and hand hygiene compliance (WHO, 2005).

The decision regarding when and what type of hand hygiene should occur depends on the following: the intensity

of contact with patients or contaminated objects, the degree or amount of contamination that could occur with that contact, the susceptibility of the patient or the health care worker to infection, and the procedure or activity to be performed (Boyce & Pittet, 2002, pp. 4–8). For example, after prolonged and direct contact with a patient's wound drainage, you must perform thorough hand hygiene.

Washing times of at least 15 seconds are needed to remove most transient microorganisms from the skin (CDC, 2007). If the hands are visibly soiled, more time may be needed. Routine handwashing may be performed with plain soap. Plain soap with water can physically remove a certain level of microbes, but antiseptic agents are necessary to kill or inhibit microorganisms and reduce the level still further (CDC, 2007). Skill 32-1 lists the steps for hand hygiene.

The use of alcohol-based waterless antiseptics is recommended by the CDC (2007) to improve hand hygiene practices, protect health care workers' hands, and reduce the transmission of pathogens to patients and personnel in health care settings. Alcohols have excellent germicidal activity and are more effective than either plain soap or antimicrobial soap and water. Emollients are added to alcohol-based antiseptics to prevent drying of the skin. Researchers have found that these antiseptics may be more effective than water because they are used quickly and are available at the bedside (Girou et al., 2002; Parienti et al., 2002).

The CDC (2007) recommended that hands be washed with plain soap or with antimicrobial soap and water when hands are visibly soiled. If your hands are not visibly soiled, use an alcohol-based waterless antiseptic agent for routine decontamination of hands in all other clinical situations:

- Before direct contact with each patient (e.g., taking a pulse or blood pressure, lifting a patient)
- After direct contact with each patient
- Before donning sterile gloves
- After removing gloves (i.e., after removing sterile gloves or clean, nonsterile gloves)
- After contact with body fluids or excretions, mucous membranes, nonintact skin, or wound dressings, as long as hands are not visibly soiled (if visibly soiled, wash with soap and water)
- When moving from a contaminated body site to a clean body site during patient care
- After contact with inanimate objects (including medical equipment) in the immediate vicinity of the patient

Alternatively, if antiseptic agents are not available, you may wash hands in all clinical situations (CDC, 2007). Also, health care workers are advised to wash their hands with soap and water if patient exposure to *C. difficile* is suspected or proven. The physical action of washing and rinsing hands under such circumstances is recommended because antiseptic agents have poor activity against spores (Louie & Meddings, 2004).

You need to instruct patients and visitors about the proper technique and times for hand hygiene. Ensure that patients and visitors understand the importance of cleaning under their nails and that artificial nails should not be worn because they harbour increased numbers of pathogens (Box 32-11). Teaching handwashing and hand hygiene is particularly important if health care is to continue at home. Patients should wash their hands before eating or handling food; after handling contaminated equipment, linen, or organic material; and after elimination. Visitors are encouraged to wash their hands before eating or handling food, after coming in contact with infected patients,

► SKILL 32-1 Handwashing/Hand Hygiene

Delegation Considerations

- Monitor an unregulated care provider (UCP) to ensure that he or she is using the proper method of hand hygiene.
- Instruct the UCP to report any skin irritation from soaps or antimicrobials.

Procedure

STEPS

1. Inspect surface of hands for breaks or cuts in skin or cuticles. Report and cover lesions before providing patient care.
2. Inspect hands for visible soiling.
3. Inspect nails for length and presence of artificial acrylics or chipped nail polish.
4. Assess patient's risk for, or extent of, infection (e.g., WBC count, extent of open wounds, known medical diagnosis).
5. Push wristwatch and long uniform sleeves above wrists. Avoid wearing rings. If worn, remove for the duration of the procedure.
6. If hands are visibly dirty or contaminated with protein-containing material, use water and plain soap or antimicrobial soap for handwashing:
 - A. Stand in front of sink, keeping hands and uniform away from sink surface. (If hands touch sink during handwashing, repeat procedure.)
 - B. Turn on water. Turn faucet on or push knee pedals laterally or press pedals with foot to regulate flow and temperature (see Step 6B illustration).

Step 6B Turn on water.

- C. Avoid splashing water against uniform.
- D. Regulate flow of water so that temperature is warm.
- E. Wet hands and wrists thoroughly under running water. Keep hands and forearms lower than elbows during washing.
- F. Apply a small amount of soap, lathering thoroughly (see Step 6F illustration). Soap granules and leaflet preparations may be used.

Equipment

- Easy-to-reach sink with warm running water
- Antimicrobial or regular soap
- Alcohol-based waterless antiseptic
- Paper towels or air dryer
- Clean orangewood stick (optional)

RATIONALE

- Open cuts or wounds can harbour high concentrations of microorganisms. Agency policy may prevent you from caring for high-risk patients. If dermatitis occurs, additional interventions may be needed.
- Lengthier handwashing is needed if soiling is heavy.
- Nails should be short and filed because most microbes on hands come from beneath the fingernails. Nails should be free of artificial applications and chipped or old nail polish (CDC, 2006). (See Box 32-11.)
- Use of alcohol-based waterless antiseptic is encouraged if you will be working with patients who are immunosuppressed (WHO, 2005).
- Provide complete access to fingers, hands, and wrists. Wearing of rings increases number of microorganisms on hands (CDC, 2006).
- Inside of sink is a contaminated area. Reaching over the sink increases the risk of touching the edge, which is contaminated.

- Microorganisms travel and grow in moisture.
- Warm water removes less of the protective oils than does hot water.
- Hands are the most contaminated parts to be washed. Water flows from least to most contaminated area, rinsing microorganisms into the sink.
- Antimicrobial soaps used exclusively can be drying to hands and can cause skin irritations. The decision of whether to use an antimicrobial soap or alcohol-based hand antiseptic should depend on the procedure to be performed and the patient's immune status.

► SKILL 32-1 Handwashing/Hand Hygiene—cont'd

- G. Wash hands using plenty of lather and friction for at least 10 to 15 seconds. Interlace fingers and rub palms and back of hands with circular motion at least five times each. Keep fingertips down to facilitate removal of microorganisms. Rub knuckles of one hand into the palm of the other; repeat with other hand (see Step 6G illustration).

Step 6F Lather hands thoroughly.

- H. Rub thumb on one hand with the palm of the other hand; repeat with other hand (see Step 6H illustration).
I. Work the fingertips on one hand into the palm of the other. Massage soap into nail spaces; repeat with other hand (see Step 6I illustration).

Step 6H Rub the thumb into the palm of the other hand. **Source:** Redrawn from World Health Organization. (2005). World Alliance for Patient Safety, *WHO Guidelines on hand hygiene in health care. Advanced draft: A summary. Clean hands are safer hands* (Handwashing technique with soap and water, p. 19, Step 6). Retrieved from http://www.who.int/patientsafety/events/05/HH_en.pdf.

- J. Areas under fingernails are often soiled. Clean them with orangewood stick or fingernails of other hand and additional soap.

- Soap cleanses by emulsifying fat and oil and lowering the surface tension of water. Friction and rubbing mechanically loosen and remove dirt and transient bacteria. Interlacing fingers and thumbs and rubbing knuckles ensure that all surfaces are cleansed.

Step 6G Rub the knuckles of one hand into the palm of the other.

Source: Redrawn from World Health Organization. (2005). World Alliance for Patient Safety, *WHO Guidelines on hand hygiene in health care. Advanced draft: A summary. Clean hands are safer hands* (Handwashing technique with soap and water, p. 19, Step 5). Retrieved from http://www.who.int/patientsafety/events/05/HH_en.pdf.

- Thumbs are frequently missed areas.
- Fingertips are frequently missed areas.

Step 6I Work the fingertips into the palm of the other hand.

Source: Redrawn from World Health Organization. (2005). World Alliance for Patient Safety, *WHO Guidelines on hand hygiene in health care. Advanced draft: A summary. Clean hands are safer hands* (Handwashing technique with soap and water, p. 19, Step 7). Retrieved from http://www.who.int/patientsafety/events/05/HH_en.pdf.

- Areas under nails can be highly contaminated, which increases the risk of infection.

Critical Decision Point: Do not tear or cut skin under or around nail.

Continued

► SKILL 32-1 Handwashing/Hand Hygiene—cont'd

video

- K. Rinse hands and wrists thoroughly, keeping hands down and elbows up (see Step 6K illustration).
- L. Optional: Repeat steps A through J and extend period of washing if hands are heavily soiled.
- M. Dry hands thoroughly from fingers to wrists and forearms with paper towel, single-use cloth, or warm-air dryer.
- N. If paper towel is used, discard it in proper receptacle.
- O. Turn off water with foot or knee pedals. To turn off hand faucet, use clean, dry paper towel; avoid touching handles with hands (see Step 6O illustration).

**Step 6K** Rinse hands.

- P. If hands are dry or chapped, a small amount of lotion or barrier cream can be applied.
 - Q. Inspect surfaces of hands for obvious signs of soil or other contaminants.
 - R. Inspect hands for dermatitis or cracked skin.
7. If hands are not visibly soiled, use an alcohol-based waterless antiseptic for routine decontamination of hands in all clinical situations.
- A. Apply an ample amount of product to palm of one hand (see Step 7A illustration).
 - B. Rub hands together, covering all surfaces of hands and fingers with antiseptic (see Step 7B illustration).

**Step 7A** Apply enough waterless antiseptic to palm of one hand to cover all hand surfaces—usually two to three pumps.

- C. Rub hands together for several seconds until alcohol is dry. Allow hands to dry before applying gloves.
- D. If hands are dry or chapped, a small amount of lotion or barrier cream can be applied.

- Rinsing mechanically washes away dirt and microorganisms.
- Drying from cleanest (fingertips) to least clean (forearms) area avoids contamination. Drying hands prevents chapping and roughened skin.
- Prevents transfer of microorganisms.
- Faucets are contaminated. Using paper towels to touch faucet prevents contamination of hands.

**Step 6O** Turn off faucet.

- Use agency-provided container of lotion because many lotions may interfere with antimicrobial action or disintegrate gloves.
- Determine whether handwashing is adequate.
- The presence of these conditions indicates complications from excessive handwashing.
- Enough product is needed to thoroughly cover the hands.
- Complete coverage of the hands and fingers by using friction ensures antimicrobial effect.

**Step 7B** Rub hands thoroughly.

- Drying ensures full antiseptic effect (Health Canada, 2007).
- Use the agency-provided container of lotion because many lotions may interfere with antimicrobial action or disintegrate gloves.

► SKILL 32-1 Handwashing/Hand Hygiene—cont'd

Recording and Reporting

- It is not necessary to record or report this procedure.
- Report any dermatitis to employee health or infection control per agency policy.

Home Care Considerations

- Evaluate the handwashing facilities in the home to determine the possibility of contamination, the proximity of the facilities to the patient, and available supplies in the area.
- Evaluate the availability of warm running water and soap when conducting home visits, and anticipate the need for alternative handwashing products such as alcohol-based hand rubs and detergent-containing towels.
- Instruct the patient and primary caregiver in the proper techniques and situations for handwashing.

* BOX 32-11 RESEARCH HIGHLIGHT

Reducing Surgical Site Infections

Research Focus

As the patient's skin is a major source of pathogenic organisms that cause surgical site infections, perhaps one solution used for surgical site preparation is more optimal in reducing postoperative infections. Researchers hypothesized that preoperative skin preparation with chlorhexidine-alcohol is more effective in preventing infection than povidone-iodine.

Research Abstract

Darouiche et al. (2010) randomly assigned adults undergoing clean-contaminated surgery at six hospitals to receive preoperative skin preparation with either 2% chlorhexidine gluconate and 70% alcohol scrub or an aqueous solution of 10% povidone-iodine scrub and then povidone-iodine paint. The patients who were eligible to be in the study were 18 years and older and were going to have clean-contaminated surgery (i.e., colorectal, small intestine, gastroesophageal, biliary, thoracic, gynecological, or urological operations). Patients were excluded if they had an allergy to chlorhexidine, alcohol, or iodophors; if there was evidence of an infection at or adjacent to the operative site; or if there was a perceived inability to follow the patient for 30 days after surgery. The patients were assessed for infection at least daily while they were in the hospital. After discharge, the patients were called once a week. If an infection was suspected, a prompt clinical assessment was done. Investigators doing the follow-up were unaware of which skin preparation product group the patients were randomized to. A total of 849 patients were randomized, 409 in the chlorhexidine-alcohol group and 440 in the povidone-iodine group. The overall surgical site infection rate was significantly lower in the chlorhexidine-alcohol group than the povidone-iodine group (9.5% versus 16.1%; $P = 0.004$; relative risk, 0.59; 95% confidence interval, 0.41 to 0.85).

Evidence-Informed Practice

- Using chlorhexidine-alcohol for preoperative preparation of the patient's skin is more effective than povidone-iodine in reducing surgical site infection after clean-contaminated surgery.

Reference: Darouiche, R. O., Wall, M. J., Itani, K. M. F., Otterson, M. F., Webb, A. L., Carrick, M. D., Miller, H. J., Awad, S. S., Crosby, C. T., Mosier, M. C., AlSharif, A., and Berger, D. H. (2010). Chlorhexidine-alcohol versus povidone-iodine for surgical site antisepsis. *New England Journal of Medicine*, 362(1), 18–26.

and after handling contaminated equipment or organic material.

Control of Portals of Entry. Many measures that control the exit of microorganisms likewise control their entrance. Maintaining the integrity of skin and mucous membranes reduces the chances of microorganisms reaching a host. The patient's skin should be kept well lubricated by using lotion as appropriate. Immobilized and debilitated patients are particularly susceptible to skin breakdown. Patients should not be positioned on tubes or objects that might cause breaks in the skin. Dry, wrinkle-free linen also reduces the chances of skin breakdown. Frequent turning and positioning are needed before a patient's skin becomes reddened. Frequent oral hygiene prevents the drying of mucous membranes. A water-soluble ointment keeps the patient's lips well lubricated.

After elimination, a woman should clean the rectum and perineum by wiping from the urinary meatus toward the rectum. Cleansing in a direction from the least to the most contaminated area helps reduce genitourinary infections. Meticulous and frequent perineal care is especially important in women who wear incontinence pads.

Patients, health care workers, and even housekeepers are at risk for acquiring infections from accidental needle sticks. After administering an injection or inserting an intravenous catheter, you should engage any safety device and carefully dispose of needles in a puncture-resistant box (see Chapter 33). A stray needle lying in the bed linen or carelessly thrown into a wastebasket is a prime source of exposure to bloodborne pathogens. Hepatitis B and C are the infections most commonly transmitted by contaminated needles. A needle stick should be reported immediately. Health care agencies require the victim of a needle stick to complete an injury report and seek appropriate treatment. The Canadian Needle Stick Surveillance Network (2003) has the mandate to monitor health care workers exposed to needle sticks and the subsequent outcomes of these exposures.

Another cause of microorganism entrance into a host is improper handling and management of urinary catheters and drainage sets (see Chapter 43). The point of connection between a catheter and drainage tube should remain closed and intact. As long as such systems are closed, their contents are considered sterile. Outflow spigots on drainage bags should also remain closed to prevent the entrance of bacteria. Movement of the catheter at the urethra should be minimized by stabilizing the catheter with tape to reduce chances of microorganisms

ascending the urethra into the bladder. Urine-measuring containers should not be shared between patients.

You may care for patients with closed drainage systems that collect wound drainage, bile, or other body fluids. In each example, the site from which a drainage tube exits should remain clear of excess moisture and accumulated drainage. All tubing should remain connected throughout use. Drainage receptacles should be opened only when it is necessary to discard or measure the volume of drainage.

At times, you will obtain specimens from drainage tubes or intravenous tubing ports. First, you must perform hand hygiene; then disinfect tubes and ports by wiping the surface outward with alcohol, iodine, or a chlorhexidine alcohol solution before entering the system. Temporarily placing squares of sterile gauze around the ends of an open drainage tube, such as a urinary catheter, adds further protection against bacteria. However, keeping drainage tubes closed and secure is the best practice.

A final method for reducing the entrance of microorganisms is the technique for cleansing wounds (see Chapter 46). A surgical wound is considered to be sterile. To prevent the entrance of microorganisms into the wound, you should clean outward from a wound site. When applying an antiseptic or cleaning with soap and water, wipe around the wound edge first and then clean outward away from the wound. Clean gauze should be used for each revolution around the wound's circumference.

Protection of the Susceptible Host. Patients' resistance to infection improves as you protect their normal body defences against infection. You can intervene to maintain the body's normal reparative processes (Box 32-12). You must also protect yourself and others by following your agency's isolation guidelines.

Isolation Guidelines. The risk of transmitting a health care-associated infection or infectious disease among patients

is high. When a patient has a suspected or known infection, health care workers are alerted and follow infection control practices. However, sometimes health care workers are not aware that patients have infections. The majority of organisms causing nosocomial infections are found in the colonized body substances of patients regardless of whether a culture has confirmed infection and a diagnosis has been made (CDC, 2007). Body substances such as feces, saliva, mucus, and wound drainage always contain potentially infectious organisms.

The CDC issued isolation guidelines in 1996 that contain a two-tiered approach (Garner, 1996). These guidelines were updated and expanded on in 2007 and have been adopted by most health care agencies. Some health care agencies have adopted Health Canada's isolation guidelines (1999), which contain a similar two-tiered approach. The Health Canada guidelines were written to accommodate acute, long-term, home, and ambulatory care settings, whereas the CDC guidelines were written specifically for acute care settings. Nevertheless, the CDC guidelines and Health Canada's guidelines are essentially interchangeable.

The first tier of the isolation guidelines contains practices designed to care for all patients in any setting, regardless of their diagnosis or presumed infectiousness (Table 32-7). In Health Canada's guidelines, it is called *routine practices*. **Routine practices** apply when a health care worker is or potentially may be exposed to (1) blood; (2) all body fluids, secretions, and excretions except sweat; (3) nonintact skin; or (4) mucous membranes. Routine practices include the appropriate use of gowns, gloves, masks, eyewear, and other protective devices or clothing. Barrier protection is indicated for use with all patients because every patient has the potential to transmit infection via blood and body fluids and the risk for infection transmission can be unknown. Routine practices also include rules on appropriate handwashing, cleaning of equipment, and disposal of contaminated linen and sharps.

The second tier of the isolation guidelines is additional precautions. These precautions are designed to contain pathogens in one area, usually the patient's room; therefore, they are often called **isolation precautions**. Only patients infected or colonized with certain highly transmissible or epidemiologically significant pathogens are placed under isolation precautions. These precautions are followed in addition to routine practices. Isolation precautions are categorized in three ways: airborne, droplet, and contact precautions (see Table 32-7). The precautions used depend on how the pathogen is spread. For example, a patient diagnosed with (or suspected of having) active tuberculosis would require the use of airborne precautions, using a special mask and ventilated room, in conjunction with routine practices.

Regardless of the category of isolation precaution (Box 32-13), you must observe the following basic principles:

- Observe thorough hand hygiene before entering and leaving the room of a patient in isolation.
- Dispose of contaminated supplies and equipment in a manner that prevents the spread of microorganisms to other persons as indicated by the mode of transmission of the organism.
- Apply knowledge of a disease process and the mode of infection transmission when using protective barriers.
- Ensure that all persons who might be exposed during transport of a patient outside the isolation room are protected.

Psychological Implications of Isolation Precautions. A patient required to be in isolation in a private room may

► BOX 32-12

Infection Control: Protecting the Susceptible Host

Protecting Normal Defence Mechanisms

Regular bathing removes transient microorganisms from the skin's surface. Lubrication helps keep the skin hydrated and intact. Regular oral hygiene removes proteins in the saliva that attract microorganisms. Flossing removes tartar and plaque that can cause infection.

Maintenance of adequate fluid intake promotes normal urine formation and a resultant outflow of urine to flush the bladder and urethral lining of microorganisms.

For physically dependent or immobilized patients, you should encourage routine coughing and deep breathing to keep patients' lower airways clear of mucus.

You should encourage proper immunization of children and adult patients (see Box 32-8).

Maintaining Healing Processes

Promote the intake of adequate fluids and a well-balanced diet containing essential proteins, vitamins, carbohydrates, and fats.

You should also use measures to increase the patient's appetite.

Promote a patient's comfort and sleep so that energy stores are replenished daily.

You can assist a patient in learning techniques to reduce stress.

► **TABLE 32-7** Health Canada Routine Practices and Additional Precautions

Routine Practices

Routine practices and precautions are for the care of all patients; they incorporate previous precautions against bloodborne pathogens (Universal Precautions) and Body Substance Isolation.

Hand hygiene must be performed before and after direct patient contact; before and after contact with the patient's environment, after contact with blood, body fluids, secretions, and excretions and after contact with equipment or articles contaminated by them; before gloves are put on and immediately after gloves are removed. (Refer to your agency's policy for use of alcohol-based waterless antiseptics.)

Gloves are worn when touching blood, body fluids, secretions, excretions, nonintact skin, mucous membranes, or contaminated items. Gloves should be removed and hand hygiene performed between care of patients. Gloves should also be changed and hand hygiene performed between procedures on the same patient and after contact with material that may be highly contaminated.

Masks, eye protection, or face shields are worn if patient care activities or procedures may generate splashes or sprays of blood or body fluid. Gowns should be used to protect uncovered skin and prevent soiling of clothing during procedures and patient care activities likely to generate a splash or spray of blood or body fluid.

Reusable patient care equipment is properly cleaned and reprocessed before use in the care of another patient. Single-use items are discarded. All soiled linen from health care facilities should be handled the same way for all patients. If the bag soaks through, an additional bag should be used.

Used sharp instruments and needles are discarded in a puncture-resistant container, which is located in the area where the item is used.

Generally, a single room is unnecessary for routine patient care. Patients who visibly soil the environment or for whom appropriate hygiene cannot be maintained should be placed in a single room with dedicated toileting facilities.

ADDITIONAL (ISOLATION) PRECAUTIONS (TIER TWO)

Category	Description and Disease	Barrier Protection
Airborne precautions	For known or suspected infections caused by microbes transmitted by airborne droplets; examples: measles, chicken pox (varicella), disseminated zoster, tuberculosis	Private room (room door kept closed), negative-pressure airflow of at least six exchanges per hour, respiratory protection device (e.g., N95 respirator) must be worn when the patient has tuberculosis or when the patient has varicella, disseminated zoster, or measles and the worker is not immune
Droplet precautions	For known or suspected infections caused by microbes transmitted by droplets produced by coughing, sneezing, or talking; examples: diphtheria (pharyngeal), rubella, influenza, pertussis, mumps, meningococcal pneumonia, or sepsis	Private room or cohort patients (room door closed unless bed is more than 2 m from the door), mask is worn when within 2 m of the patient
Contact precautions	For known or suspected infections caused by direct or indirect contact; examples: colonization or infection with multidrug-resistant organisms; <i>C. difficile</i> ; major wound infections; gastrointestinal, respiratory, or skin infections	Private room or cohort patients (door can be open); gloves and gown upon entry into isolation room; limiting patient movement outside of isolation room to necessary medical treatments or procedures; cleaning and disinfecting or discarding items before removal from isolation room

► BOX 32-13 Procedural Guideline

Caring for a Patient on Isolation Precautions

Delegation Considerations:

Care of a patient in isolation can be delegated to an unregulated care provider (UCP) when necessary procedures are within the UCP's competence.

Equipment:

- Barrier protection determined by type of isolation
- Supplies necessary for procedures performed in room

Procedure:

1. Assess isolation indications (e.g., current laboratory test results or the patient's history of exposure).

2. Review agency policies and precautions necessary for the specific isolation category, and consider care measures to be performed while in the patient's room.
3. Review nurses' notes or confer with colleagues regarding the patient's emotional state and adjustment to isolation.
4. Perform handwashing and hand hygiene and prepare all equipment to be taken into the patient's room.
5. Prepare for entrance into isolation room:
 - A. Perform handwashing and hand hygiene.
 - B. Apply gown (when needed), making sure it covers you from neck to knees. Pull sleeves down to wrist. Tie securely at neck and waist (see Step 5B illustration).

Continued

► BOX 32-13 Procedural Guideline—cont'd

Step 5B Tie gown at waist.

- C. Apply either surgical mask or respirator around mouth and nose when needed. (Type will depend on type of isolation and facility policy.)
- D. Apply eyewear or goggles snugly and adjust to fit around face and eyes (when needed).
- E. Apply disposable nonsterile gloves for isolation. (Note: Unpowdered, latex-free gloves should be worn if the patient or the health care worker has a latex allergy.) If gloves are worn with a gown, bring the glove cuffs over edge of the gown sleeves.
- 6. Enter the patient's room. Arrange supplies and equipment. (If equipment will be removed from room for reuse, place it on a clean paper towel.)
- 7. Explain purpose of isolation and necessary precautions to the patient and family. Offer an opportunity to ask questions. Assess for evidence of emotional problems that may be caused by being in isolation.
- 8. Assess vital signs:
 - A. If patient is infected or colonized with a resistant organism (e.g., vancomycin-resistant enterococci [VRE] or methicillin-resistant *Staphylococcus aureus* [MRSA]), the equipment remains in room. Proceed to assess vital signs. Avoid contact of stethoscope or blood pressure cuff with infectious material.
 - B. If stethoscope is to be reused, the entire stethoscope must be thoroughly cleaned after leaving the room. You may use a few alcohol swabs to clean and disinfect the stethoscope. (Ideally, equipment is dedicated for the use of the patient with an antibiotic-resistant organism and remains in the room.) Clean diaphragm or bell with alcohol. Set aside on clean surface.
 - C. Individual or disposable thermometers should be used.
- 9. Administer medications:
 - A. Give oral medication in wrapper or cup.
 - B. Dispose of wrapper or cup in plastic-lined receptacle.
 - C. Administer injection.
 - D. Discard syringe and uncapped needle or sheathed needle into special container.
 - E. If gloves are not worn and hands contact contaminated article or body fluids, wash hands immediately.

- 10. Administer hygiene measures, encouraging the patient to discuss questions or concerns about isolation. Informal teaching can be used at this time:
 - A. Prevent the gown from becoming wet.
 - B. Remove linen from the bed; avoid contact with the gown. Place linen in an impervious bag.
 - C. Change gloves and wash your hands if they become excessively soiled and further care is necessary.
- 11. Collect specimens:
 - A. Place specimen containers on a clean paper towel in the patient's bathroom.
 - B. Follow procedure for collecting specimen of body fluids.
 - C. Transfer specimen to the container without soiling the outside of the container. Place the container in a plastic bag, and place a label on the outside of the bag or as per agency policy.

Step 12B Tie linen securely.

- 12. Dispose of linen and garbage bags as they become full:
 - A. Use sturdy, moisture-resistant single bags to contain soiled articles.
 - B. Tie bags securely at the top in a knot (see Step 12B illustration).
- 13. Resupply room as needed.
- 14. When leaving isolation room, remove personal protective equipment, except for N95 respirator, inside doorway or in anteroom. Remove N95 respirator after leaving the patient's room and closing the door.
 - A. Remove gloves. Remove one glove by grasping the cuff and pulling the glove inside out over the hand. Discard the glove. With the ungloved hand, tuck a finger inside the cuff of the remaining glove and pull it off, inside out.
 - B. Perform handwashing and hand hygiene.
 - C. Untie waist and neck strings of the gown. Allow the gown to fall from your shoulders. Remove hands from sleeves without touching the outside of the gown (see Step 14C illustration). Hold the gown inside at shoulder seams and fold inside out; discard in laundry bag.

► BOX 32-13 Procedural Guideline—cont'd

Step 14C Remove hands from sleeves without touching outside of the gown.

D. Perform hand hygiene.

E. Untie first bottom mask string and then top strings; pull the mask away from your face, and drop the mask into a waste receptacle (see Step 14E illustration). (Do not touch outer surface of mask.)

Step 14E Remove mask away from face.

F. Remove eyewear or goggles.

G. Perform handwashing and hand hygiene.

H. Explain to the patient when you plan to return to the room. Ask whether the patient requires any personal-care items, books, or magazines.

I. Leave the room and close the door, if necessary. (Door should be closed if airborne precautions are being used.)

J. All contaminated supplies and equipment should be disposed of in a manner that prevents the spread of microorganisms to other individuals (see your agency's policy).

* BOX 32-14 RESEARCH HIGHLIGHT

Adverse Effects of Isolation

Research Focus

Stelfox et al. (2003) studied whether patients who are isolated in single rooms experience adverse effects as a result of the isolation.

Research Abstract

A Canadian and an American hospital were included in a study to examine the likelihood of adverse events. Patients who were cared for in isolation because they were infected with MRSA were compared with those who were not isolated. The research found that (1) isolated patients were more likely to complain about care than were nonisolated patients (8% versus 1%); (2) vital signs were not recorded on charts as ordered as often for isolated patients as for nonisolated patients (51%

versus 31%); (3) nurses were less likely to record nursing notes for isolated patients (14% versus 10%); and (4) patients in isolation were eight times more likely to experience falls, pressure ulcers, and fluid or electrolyte disorders.

Evidence-Informed Practice

- You must be extra vigilant to ensure the standard of care is similar for all patients, including those on isolation precautions.
- You should ensure that both physical and psychological factors are addressed when planning and carrying out care for isolated patients.
- You must ensure that you record observations and complete nursing notes for all patients, including those in isolation.

Reference: Stelfox, H. T., Bates, D. W., & Redelmeir, D. A. (2003). Safety of patients isolated for infection control. *Journal of the American Medical Association*, 290, 1899–1905.

become lonely because normal social relationships are disrupted. This situation can be psychologically harmful, especially for children (Box 32-14).

Patients' body image may be altered as a result of the infectious process. Patients may feel unclean, rejected, lonely, or guilty. Infection prevention and control practices further intensify these feelings of difference or undesirability. Isolation in a private room limits sensory contact. Unless you act to minimize feelings of psychological and physical isolation, your patients' emotional state can interfere with their recovery.

Before isolation measures are instituted, a patient and family must understand the nature of the disease or condition, purposes of isolation, and steps for carrying out specific precautions. If they are able to participate in maintaining infection prevention, the chances of reducing the spread of infection are increased. The patient and family should be taught to perform hand hygiene and use barrier protection if appropriate. Each procedure should be demonstrated, and the patient and family should be given an opportunity to practise it. It is also important to explain how infectious organisms can be transmitted so

that the patient understands the difference between contaminated and clean objects.

You should take measures to improve the patient's sensory stimulation during isolation. The room environment should be clean and pleasant. Drapes or shades should be opened, and excess supplies and equipment removed. You must listen to the patient's concerns or interests. If you hurry through care or show a lack of interest, the patient will feel rejected and even more isolated. Mealtime is a particularly good opportunity for conversation. Providing comfort measures such as repositioning, a back massage, or a tepid sponge bath increases physical stimulation. If appropriate for the patient's condition, you should encourage the patient to walk and to sit up in a chair. Recreational activities such as board games or cards may be an option to keep the patient mentally stimulated.

You must explain to the family the patient's risk for depression or loneliness. Visiting family members should be taught the principles of isolation and encouraged to avoid expressions or actions that convey revulsion, fear, or disgust. Discuss ways to provide meaningful stimulation.

Protective Environment. Private rooms used for isolation may have negative-pressure airflow to prevent infectious particles from flowing out of the room. Special rooms with positive-pressure airflow are used for highly susceptible patients, such as organ transplant recipients. On the door or wall outside the room, post a card listing the precautions for the isolation category according to your agency's policy. The card is a handy reference for health care workers and visitors, and it alerts anyone who might enter the room that special precautions must be followed.

The isolation room or an adjoining anteroom should contain hand hygiene, bathing, and toilet facilities. Soap and antiseptic solutions must be made available. Personnel and visitors perform hand hygiene before approaching the patient's bedside and again before leaving the room. If toilet facilities are unavailable, special procedures for handling portable commodes, bedpans, or urinals must be followed. Personal protective equipment should be stored in an anteroom between the room and hallway or in a convenient location close to the point of use.

All patient care rooms, including those used for isolation, contain an impervious bag for soiled or contaminated linen as well as a waste receptacle with plastic liners. Impervious receptacles stop the transmission of microorganisms by preventing seepage and soiling of the outside surface. A disposable rigid container should be available in the room for discarding of used needles, syringes, and sharp objects.

You should remain aware of infection prevention and control techniques while working with patients in protected environments. Depending on the microorganism and the mode of transmission, you must evaluate what articles or equipment may be taken into an isolation room. For example, Health Canada (2007) recommends the dedicated use of articles such as stethoscopes, sphygmomanometers, and rectal thermometers in the isolation room of a patient infected or colonized with vanomycin-resistant enterococci (VRE). These devices should not be used on other patients unless the devices are first adequately cleaned and disinfected. If you bring an article into the room, expose the article to infected material, and then touch or remove the article, you increase the risk of transmitting infection to other patients or personnel.

Personal Protective Equipment. Personal protective equipment (gowns, masks, protective eyewear, and gloves) should be readily available. The primary reason for gowning is to

prevent the contamination of clothes during contact with the patient. Gowns and coverups protect health care workers and visitors from coming in contact with infected material, blood, or body fluid. Gowns may also be required for contact precautions, depending on the expected amount of exposure to infectious material. Gowns used for barrier protection are made of a fluid-resistant material and should be changed immediately if damaged or heavily contaminated.

Isolation gowns usually open at the back and have ties or snaps at the neck and waist to keep the gown closed and secure. They should be long enough to cover all outer garments. Long sleeves with tight-fitting cuffs provide added protection. No special technique is required for applying clean gowns as long as they are fastened securely. However, you must be careful when removing a gown to minimize the contamination of your hands and uniform. Isolation gowns are disposable or reusable, depending on your agency's policy.

Full face protection (with eyes, nose, and mouth covered) should be worn when splashing or spraying of blood or body fluid into the face is possible. Masks and eye protection should also be worn when working with a patient placed on droplet precautions; they protect you from inhaling microorganisms from a patient's respiratory tract and prevent the transmission of pathogens from your respiratory tract to the patient. Surgical masks protect a wearer from inhaling large-particle aerosols that travel short distances (2 m). Eye protection protects a wearer from receiving large-particle droplets to the eye. At times, a patient who is susceptible to infection wears a mask to prevent inhalation of pathogens. Patients on droplet or airborne precautions who are transported outside of their rooms should wear masks to protect other patients and personnel. According to the CDC (2007), masks may prevent the transmission of infection through direct contact with mucous membranes. In addition, masks discourage the wearer from touching the eyes, nose, or mouth.

A properly applied mask fits snugly over the mouth and nose so that pathogens and body fluids cannot enter or escape through the sides (Box 32-15). If a person wears glasses, the top edge of the mask fits below the glasses so that the glasses do not cloud over as the person exhales. Talking should be kept to a minimum while wearing a mask to reduce respiratory airflow—a mask that has become moist may not provide a barrier to microorganisms and should be discarded. A mask should never be reused. Patients and family members should be warned that a mask can cause a sensation of smothering. If family members become uncomfortable wearing a mask, they should leave the room and discard the mask.

Specially fitted respiratory protective devices or masks are required when you care for a patient with known or suspected tuberculosis or when the patient has varicella, disseminated zoster, or measles and the worker is not immune. The mask must have a higher filtration rating than the regular surgical mask and be fitted snugly to the wearer's face to prevent leakage around the sides. You should be aware of your agency's policy regarding the type of respiratory protective device required.

Gloves help to prevent the transmission of pathogens by direct and indirect contact. Clean, nonsterile gloves (also called disposable gloves) should be worn when contact with blood, body fluid, secretions, excretions, or contaminated items is possible. Clean gloves should be donned just before you touch mucous membranes and nonintact skin. Gloves should be changed between tasks and procedures on the same patient

► BOX 32-15 Procedural Guideline

Donning a Surgical-Type Mask

Procedure:

1. Find top edge of the mask (usually has a thin metal strip). The pliable metal fits snugly against bridge of nose.
2. Hold the mask by top two strings or loops. Tie the two top ties at the top of back of the head (see Step 2 illustration), with ties above ears (alternative: slip loops over each ear).

Step 2 Tie two top ties at top of back of head.

3. Tie the two lower ties snugly around the neck, with mask well under chin (see Step 3 illustration).

Step 3 Tie two lower ties snugly around the neck.

4. Gently pinch upper metal band around bridge of nose.

Note: Mask should be changed if it becomes wet, moist, or contaminated.

after contact with material that may contain a high concentration of microorganisms. Gloves should be removed promptly after use, before touching noncontaminated items and environmental surfaces, and before going to another patient. Hand hygiene should be performed immediately after removing the gloves to avoid the transfer of microorganisms to other patients and environments. Facilities provide nonlatex gloves for health care staff who are allergic or sensitive to latex. When full protective apparel is needed, you must first perform hand hygiene, apply a mask and eyewear or goggles (as needed), apply a gown, and then put on gloves. Disposable gloves are easily applied and are designed to fit either hand. The glove cuffs should be pulled up over the wrists or over the cuffs of the gown. The gloves' thin rubber can be easily torn; if a break or tear is detected in a glove while providing care, you should change gloves if care is not completed. If you do not plan to have more contact with the patient, reapplying gloves is unnecessary.

Family members visiting patients who are in isolation that necessitates the use of gloves must know when and how to apply gloves properly. You need to demonstrate the application of gloves to family members and explain the reason for glove use. Emphasize the importance of hand hygiene after the removal of gloves.

When participating in a procedure that may create droplets or splashing or spraying of blood or other body fluids, you must wear protective eyewear and a mask or a face shield (CDC, 2007). Examples of such procedures are the irrigation of a large abdominal wound or the insertion of an arterial catheter in which you assist a physician. Eyewear may be available in the form of plastic glasses or goggles. They should fit snugly around the face so that fluids cannot enter between the face and the glasses.

Specimen Collection. Often, many laboratory studies are required when a patient is suspected of having an infectious disease. Body fluids and secretions suspected of containing infectious organisms are collected for culture and sensitivity

tests. The specimen is placed in a medium that promotes the growth of organisms. A laboratory technologist then identifies the microorganisms growing in the culture. Additional test results indicate antibiotics to which the organisms are resistant or sensitive, and sensitivity reports determine the antibiotics to be used in treatment.

You need to obtain all culture specimens using disposable gloves and sterile equipment. Collecting fresh material from the site of the infection, such as wound drainage, ensures that the specimen is not contaminated by neighbouring microbes. All specimen containers should be sealed tightly to prevent spillage and contamination of the outside of the container. Box 32-16 describes the techniques for collecting specimens from a patient with a suspected infection.

Bagging Waste or Linen. You should use special bagging procedures when removing contaminated items from a patient's environment. Bagging contaminated items and ensuring the outside of the bag is not contaminated prevents accidental exposure of personnel and contamination of the surrounding environment.

Health Canada (2007) recommends using a single bag for discarding items if the bag is impervious and sturdy and if the article can be placed in the bag without contaminating the outside of the bag. Soiled linen should be placed in an impervious laundry bag in the patient's room. Health Canada (2007) recommends double bagging *only* if it is impossible to prevent the contamination of the bag's outer surface. Studies have shown that double bagging is otherwise not necessary to control infection (Maki et al., 1986; CDC, 2007). The use of one standard-sized linen bag that is not overfilled, is tied securely, and is intact is adequate to prevent infection transmission. The same rule applies to garbage bags.

Transporting Patients. Before transferring patients to wheelchairs or stretchers, give them clean gowns to serve as robes. Patients infected with organisms transmitted by the airborne route should leave their rooms only for essential purposes, such as diagnostic procedures or surgery. These patients

► BOX 32-16 Specimen Collection Techniques*

Wound Specimen

Clean the site with sterile water or saline before wound specimen collection. Wear gloves and use a cotton-tipped swab or a syringe to collect as much drainage as possible. Set a clean test tube or culture tube on a clean paper towel close by. After swabbing the centre of the wound site, grasp the collection tube by holding it with a paper towel. Carefully insert the swab without touching the outside of the tube. After securing the tube's top, transfer the tube into a bag for transport and then perform hand hygiene.

Blood Specimen

Wearing gloves, use a syringe and culture media bottles to collect up to 10 mL of blood per culture bottle (check your agency's policy about exact amounts required). After prepping the patient, perform a venipuncture at two different sites to decrease the likelihood of both specimens being contaminated with skin flora. Place the blood culture bottles on the bedside table or another surface; swab off the bottle tops with alcohol. Inject the appropriate amount of blood into each bottle. Remove your gloves and transfer the specimen into a clean, labelled bag for transport. Perform handwashing and hand hygiene.

Stool Specimen

Wearing gloves, use a clean cup with sealing top (it does not need to be sterile) and a tongue blade to collect a small amount of stool, approximately the size of a walnut: place the cup on a clean paper towel in the patient's bathroom; using the tongue blade, collect the needed amount of feces from the patient's bedpan; transfer the feces to the cup without touching the cup's outside surface. Dispose of the tongue blade, and place the seal on the cup. Transfer the specimen into a clean bag for transport. Remove your gloves and perform hand hygiene.

Urine Specimen

Wearing gloves, use a syringe and sterile cup or tube to collect 1 to 5 mL of urine. Place the cup or tube on a clean towel in the patient's bathroom. If the patient has a urinary catheter, use the syringe to collect the specimen. If the patient is not catheterized, have the patient follow the procedure to obtain a clean voided specimen (see Chapter 43). Transfer the urine into a sterile container by injecting urine from the syringe or by pouring it from the used collection cup. Secure the top of the container and transfer the specimen into a clean, labelled bag for transport. Remove your gloves and perform hand hygiene.

*Agency policies may differ on the type of containers and amount of specimen material required.

Adapted from Pagana, K. D., & Pagana, T. J. (2010). *Mosby's manual of diagnostic and laboratory tests* (4th ed.). St Louis, MO: Mosby.

must also wear masks. Personnel transporting these patients should also wear barrier protection as needed.

At times, a patient being transported may drain body fluids onto a stretcher or wheelchair. When this occurs, you must be sure to have the equipment cleaned and, if necessary, disinfected after the patient returns to the room. An extra layer of sheets may be used to cover the stretcher or seat of the wheelchair.

Personnel in diagnostic or procedural areas or the operating room should be notified that the patient is on isolation precautions. Record the type of isolation on the patient's chart. Explain to the patient ways that he or she can help prevent the transmission of infection during transport. A patient on airborne

or droplet isolation is provided with a mask and given tissues and a bag to allow for the proper disposal of secretions.

Role of the Infection Control Professional. Many hospitals employ professionals who are specially trained in infection prevention and control; most of these professionals are nurses. These individuals are responsible for advising hospital personnel regarding infection prevention and control and for monitoring infections within the hospital. The Community and Hospital Infection Control Association of Canada (CHICA-Canada) is a voluntary multidisciplinary association of infection control professionals. Its mission is to promote excellence in the practice of infection prevention and control (CHICA-Canada, 2004). The duties of an infection control professional include the following:

- Provide staff with education on infection prevention and control.
- Develop and review infection prevention and control policies and procedures.
- Recommend appropriate isolation procedures.
- Screen patient records for community-acquired infections that may be reportable to the public health department.
- Consult with employee health departments concerning recommendations to prevent and control the spread of infection among personnel, such as tuberculosis testing.
- Gather statistics regarding the **epidemiology** (cause and effect) of HAIs.
- Notify the public health department of incidents of communicable diseases within the facility.
- Confer with all hospital departments to investigate unusual events or clusters of infection.
- Recommend education for patients and families
- Identify infection control problems related to equipment.
- Monitor antibiotic-resistant organisms in the institution.
- Monitor construction sites in hospitals to ensure that appropriate dust containment measures are used.

An infection control professional can be a valuable resource for nurses in controlling nosocomial infections.

Infection Prevention and Control for Hospital Personnel. Health care workers are continually at risk of exposure to infectious microorganisms. Each agency has protocols in place to advise staff and to monitor infection protocols. Hospitals offer regularly scheduled staff education programs. Each province and territory has rules and procedures to ensure that health care workers are not unnecessarily exposed to pathogens.

Patient Education. Often patients must learn to use infection control practices at home (Box 32-17). Preventive technique will become almost second nature to you if practised daily, but your patients will be less aware of factors that promote the spread of infection and ways to prevent its transmission. The home environment does not always lend itself to infection prevention—often you must help patients adapt according to the resources available to maintain hygienic techniques. However, patients in a home care setting generally have a lower risk of infection than do patients in a hospital because they have less exposure to resistant organisms and undergo fewer invasive procedures.

Surgical Asepsis. Surgical asepsis, or sterile technique, requires precautions different from those of medical asepsis. Surgical asepsis includes procedures used to eliminate all microorganisms, including pathogens and spores, from an object or area. In surgical asepsis, an area or object is considered contaminated if touched by any object that is not sterile.

* BOX 32-17 PATIENT TEACHING

Infection Control

Objective

- Patient will perform self-care using proper infection control techniques.

Teaching Strategies

- Instruct the patient about cleaning equipment using soap and water and disinfecting it with an appropriate disinfectant.
- Demonstrate proper hand hygiene, explaining that it should be done before and after all treatments and when infected body fluids are contacted.
- Instruct the patient about the signs and symptoms of wound infection.
- For patients who receive tube feedings at home, explain the importance of preparing enough formula for only eight hours (in the case of commercially prepared foods) or four hours (in the case of home-prepared foods). Tell the patient that contaminated enteral feedings can cause infections. Teach the patient to rinse the feeding bag and tubing with mild soap and water daily and to dry them.
- Instruct the patient to place contaminated dressings and other disposable items containing infectious body fluids in impervious plastic bags and to place needles in a puncture-proof and leak-proof container, such as an empty bleach bottle with the opening taped shut or a coffee can with the lid taped closed. Glass containers should not be used. Ensure that the patient knows to contact the local municipality or public health department before disposing of contaminated items (Health Canada, 2007).

- Instruct the patient (or family) to separate noticeably soiled linen from other laundry, wash it in water that is as hot as the fabric will tolerate, add 250 mL of bleach to detergent, and set the dryer temperature as high as the fabric will allow.

Evaluation

- Ask the patient or family member to describe techniques used to reduce the transmission of infection.
- Ask the patient to demonstrate select techniques.
- Ask the patient to explain the risks for infection based on the condition.

After patients are at home, you need to educate them about infection and techniques to prevent or control its spread, and you need to determine their compliance with infection control practices. Family members caring for patients must be involved in the teaching plan—teach patients and family members a common-sense approach to controlling and preventing infection. Topics to address in a teaching session include the following:

- The patient's susceptibility to infection
- The chain of infection, with specific reference to the means of transmission
- Hygienic practices that minimize organism growth and spread; emphasize handwashing
- Preventive health care (e.g., proper diet, immunizations, and exercise)
- The proper methods for handling and storage of food
- An awareness of family members who are at risk for acquiring infection

While you are working with a sterile field or with sterile equipment, you must understand that the slightest break in technique results in contamination. Surgical asepsis should be used in the following situations:

- During procedures that require the intentional perforation of the patient's skin (e.g., the insertion of intravenous catheters or administration of injections)
- When the skin's integrity is broken as a result of trauma, surgical incision, or burns
- During procedures that involve the insertion of catheters or surgical instruments into sterile body cavities

Although surgical asepsis is commonly practised in the operating room, labour and delivery area, and major diagnostic areas, you may also use surgical aseptic techniques at the patient's bedside, for example, when inserting intravenous or urinary catheters, suctioning the tracheobronchial airway, or reapplying sterile dressings. In an operating room, you must follow a series of steps to maintain sterile technique, including applying a mask, protective eyewear, and a cap; performing a surgical hand scrub; and applying a sterile gown and gloves. In contrast, when performing a dressing change at a patient's bedside, you may only perform hand hygiene and apply sterile gloves (see Principles of Surgical Asepsis section). When using the principles of surgical asepsis, remember you are trying to prevent infections. For more information on infection control, see Box 32-18.

Patient Preparation. Because surgical asepsis necessitates exact techniques, you must have the patient's cooperation. Therefore, you must prepare the patient before any procedure. Some patients may fear moving or touching objects during a sterile procedure, but others may try to assist. You

need to explain how a procedure is to be performed and what the patient can do to avoid contaminating sterile items, including the following:

- Avoid sudden movements of body parts covered by sterile drapes.
- Refrain from touching sterile supplies, drapes, or the nurse's gloves and gown.
- Avoid coughing, sneezing, or talking over a sterile area.

Certain sterile procedures may take an extended period of time. You should assess the patient's needs and anticipate factors that may disrupt a procedure. If a patient is in pain, try to administer analgesics no more than half an hour before a sterile procedure begins. Give the patient the opportunity to void. Often patients must assume uncomfortable positions during sterile procedures. Help the patient to assume the most comfortable position possible. Finally, the patient's condition may result in actions or events that contaminate a sterile field. For example, a patient with a respiratory infection transmits organisms by coughing or breathing; you need to anticipate such a problem and offer the patient a mask.

Principles of Surgical Asepsis. When beginning a surgically aseptic procedure, you must follow certain principles to ensure the maintenance of asepsis. Failure to follow these principles places patients at risk for infection. The following principles are important:

1. *A sterile object remains sterile only when touched by another sterile object.* This principle guides you in the placement of sterile objects and how to handle them.
 - A. Sterile objects that touch sterile objects remain sterile; for example, sterile gloves are worn or sterile forceps are used to handle objects on a sterile field.

► BOX 32-18 Surgical Asepsis: Infection Control

Objective

- The goal of surgical asepsis or aseptic technique is to prevent microorganisms from becoming introduced to a susceptible site. It should also prevent transmission of microorganisms to other patients or to staff.

Principles

- Ensure that all required supplies are gathered and that there is a clear and dry field to carry out the procedure.
 - Movement within or around a sterile field should be done in a manner that does not contaminate the sterile field.
 - Sterile fields should be prepared as close to the time of use as possible; the potential for environmental contamination from dust and particles in the ambient environment that settle on surfaces increases over time.
 - Conversation in a sterile field should be kept to a minimum to reduce contamination by means of respiratory droplets.
 - Perform hand hygiene prior to setting up a sterile field.
 - Ensure the sterile barrier covering the supplies is intact, with no punctures or evidence of moisture damage.
 - If there is any question of the item's sterility, the item must be considered unsterile.
 - Open sterile packs carefully to prevent contamination of the contents of the pack.
 - All items in a sterile field must be sterile.
 - Once a sterile package is opened, a 2.5 cm border around the edges is considered unsterile.
 - Pour solutions into receptacles on the sterile field slowly to avoid splashing. Splashing can cause strike-through or splash-back from nonsterile surfaces to the sterile field.
 - An object is considered to be no longer sterile if it is below a person's waist or if it is out of the range of vision.
 - Wear sterile gloves for the procedure to prevent the introduction of microorganisms to the site and to protect the wearer from coming into contact with body fluids.
- B. Sterile objects that touch clean objects become contaminated; for example, if the tip of a syringe or other sterile object touches the surface of a clean disposable glove, the object is contaminated.
 - C. Sterile objects that touch contaminated objects become contaminated; for example, when you touch a sterile object with an ungloved hand, the object is contaminated.
 - D. Sterile objects that touch questionable objects are considered contaminated; for example, when a tear or break in the covering or packaging of a sterile object is found, the object is discarded regardless of whether the object itself appears untouched.
2. *Only sterile objects may be placed on a sterile field.* All items are properly sterilized before use. Sterile objects are kept in clean, dry storage areas. The package or container holding a sterile object must be intact and dry—a package that is torn, punctured, wet, or open is considered to be contaminated.
 3. *A sterile object or field out of the range of vision or an object held below a person's waist is contaminated.* You must never turn your back on a sterile tray or leave it unattended. Contamination can occur accidentally by a dangling piece of clothing, falling hair, or an unknowing patient touching a sterile

Figure 32-2 Placing sterile item on a sterile field.

object. Any object held below waist level is considered contaminated because it cannot be viewed at all times. Sterile objects should be kept in front of you with your hands as close together as possible.

4. *A sterile object or field becomes contaminated by prolonged exposure to air.* You need to avoid activities that may create air currents, such as excessive movements or rearranging linen after a sterile object or field becomes exposed. When sterile packages are being opened, it is important to minimize the number of persons walking into the area. Microorganisms travel by droplet through the air; therefore, no one should talk, laugh, sneeze, or cough over a sterile field or when gathering and using sterile equipment. Microorganisms travelling through the air can fall on sterile items or fields if you reach over the work area. When opening sterile packages, hold the item or piece of equipment as close as possible to the sterile field without touching the sterile surface. Keeping the movement or rearranging of sterile items to a minimum also reduces contamination by air transmission.
5. *When a sterile surface comes in contact with a wet, contaminated surface, the sterile object or field becomes contaminated by capillary action.* If moisture seeps through a sterile package's protective covering, microorganisms travel to the sterile object. When stored sterile packages become wet, you must discard the objects immediately or send the equipment for resterilization. When working with a sterile field or tray, you may have to pour sterile solutions. Any spill can be a source of contamination unless the object or field rests on a sterile surface that cannot be penetrated by moisture. Urinary catheterization trays contain sterile supplies that rest in a sterile, plastic container. In this example, sterile solutions spilled within the container will not contaminate the catheter or other objects. In contrast, if you place a piece of sterile gauze in its wrapper on a patient's bedside table and the table surface is wet, the gauze is considered contaminated.
6. *Fluid flows in the direction of gravity.* A sterile object becomes contaminated if gravity causes a contaminated liquid to flow over the object's surface. To avoid contamination during a surgical hand scrub, hold your hands above the elbows. This allows water to flow downward without contaminating your hands and fingers. This is also the reason for drying from the fingers to elbows with hands held up, after the scrub.
7. *The edges of a sterile field or container are considered to be contaminated.* Frequently, sterile objects are placed on a sterile towel or drape (Figure 32-2). Because the edge of the drape

touches an unsterile surface, such as a table or bed linen, a 2.5-cm border around the drape is considered contaminated. Objects placed on the sterile field must be inside this border. The edges of sterile containers become exposed to air after they are open and are thus contaminated. After a sterile needle is removed from a container, the objects must not touch the container's edge. The lip of an opened bottle of solution also becomes contaminated after it is exposed to air. When pouring a sterile liquid, first pour a small amount of solution to wash away microorganisms on the bottle lip. This small amount of solution is then discarded; pour a second time on the same side to fill a container with the desired amount of solution.

Performing Sterile Procedures. All necessary equipment should be assembled before a procedure so that you avoid having to leave a sterile area to obtain equipment. A few extra supplies should be available in case objects accidentally become contaminated. Before the sterile procedure, each step should be explained so that the patient can cooperate fully. If an object becomes contaminated during the procedure, you should discard it immediately.

Donning and Removing Caps, Masks, and Eyewear. For sterile procedures on a general nursing division, you may wear a surgical mask and eyewear without a cap. Eyewear is worn as a part of standard precautions or routine practices if fluid or blood could splash into your eyes. For sterile surgical procedures, you must first apply a clean cap that covers all the hair and then put on the surgical mask and eyewear. The mask must fit snugly around the face and nose to prevent contamination by droplet nuclei. After a mask is worn for several hours, the area over the mouth and nose often becomes moist. Because moisture promotes the spread of microorganisms, the mask should be changed if it becomes moist.

Protective glasses or goggles should fit snugly around the forehead and face to fully protect the eyes. Eyewear needs to be worn only for procedures that create the risk of body fluids splashing into the eyes.

Before removing a mask, eyewear, and cap, remove the gloves to prevent contamination of the hair, neck, and facial area. After untying the mask, hold it by the ties and discard it with the cap. Masks should not be worn hanging from the neck after removal from the face. Eyewear is removed and cleaned later for reuse. After removing all protective wear, perform handwashing and hand hygiene thoroughly.

Opening Sterile Packages. Sterile items such as syringes, gauze dressings, and catheters are packaged in paper or plastic containers that are impervious to microorganisms as long as they are dry and intact. Some institutions wrap reusable supplies in a double thickness of paper, linen, or muslin. These packages are permeable to steam and thus allow for steam autoclaving. Sterile items are kept in clean, enclosed storage cabinets and are separated from nonsterile equipment.

Sterile supplies carry chemical tapes indicating that a sterilization process has taken place. The tapes change colour during the sterilization process; if the tapes do not change colour, the item is not sterile. A sterile item should never be used if the integrity of the packaging is compromised. Health care facilities may apply the date processed and a lot number to the item after processing ("event-related expiration"), or they may apply an expiration date ("date-related expiration") to the item. With either system, it is important for you to check the integrity of the packaging before using an item.

Figure 32-3 Opening a sterile package on a cleaned work area above waist level.

Before opening a sterile item, perform thorough handwashing and hand hygiene. Inspect the supplies for package integrity and sterility and assemble the supplies in the work area, such as the bedside table or treatment room, before opening the packages. A cleaned bedside table or countertop provides a large, clean working area for opening items. The work area should be above waist level. Sterile supplies should not be opened in a confined space where a dirty object might fall on or strike them.

Opening a Sterile Item on a Flat Surface. Sterile packaged items must be opened without contaminating the contents. Commercially packaged items are usually designed so that you have to tear away or separate only the paper or plastic cover. The item is held in one hand while the wrapper is pulled away with the other (Figure 32-3). Take care to keep the inner contents sterile before use. When opening items processed by the facility and packed in paper or linen, observe the following steps:

1. Place the item flat in the centre of the work surface.
2. Remove the sterilization tape or seal.
3. Grasp the outer surface of the tip of the outermost flap.
4. Open the outer flap away from the body, keeping the arm outstretched and away from the sterile field (Figure 32-4, A).
5. Grasp the outside surface of the first side flap.
6. Open the side flap, allowing it to lie flat on the table surface. Keep your arm to the side and not over the sterile surface (see Figure 32-4, B). Do not allow the flaps to spring back over the sterile contents.
7. Grasp the outside surface of the second side flap and allow it to lie flat on the table surface (see Figure 32-4, C).
8. Grasp the outside surface of the last and innermost flap.
9. Stand away from the sterile package and pull the flap back, allowing it to fall flat on the surface (see Figure 32-4, D).
10. Use the inner surface of the package (except for the 2.5-cm border around the edges) as a sterile field to add additional sterile items. The 2.5-cm border can be grasped to manoeuvre the field on the table surface.

If the sterile supplies are not for immediate use, you can close the sterile package. In this case, touch only the wrapper's outside surface. To close a package, the order of unwrapping is reversed, and you should not touch the inside contents or reach over the field.

Opening a Sterile Item While Holding It. To open a small, sterile item, hold the package in your nondominant hand. Using the dominant hand, carefully open the side and top flaps away from the enclosed sterile item in the order previously mentioned. Open the item in a hand so that the item can be

handed to a person wearing sterile gloves or transferred to a sterile field.

Preparing a Sterile Field. When performing sterile procedures, you need a sterile work area that provides room for the handling and placing of sterile items. A **sterile field** is an area

free of microorganisms and prepared to receive sterile items. The field may be prepared by using the inner surface of a sterile wrapper as the work surface or by using a sterile drape or dressing tray. Skill 32-2 describes preparation of a sterile field. After the surface for the field is created, add sterile items

Figure 32-4 Opening sterile packaged items on a flat surface. **A**, Open the top flap away from the body. **B**, Keep your arm away from the sterile field while opening the side flap. **C**, Open the second side flap. **D**, Open the back flap.

► SKILL 32-2 Preparation of a Sterile Field

video

Delegation Considerations

Delegation of the preparation of a sterile field is inappropriate unless you are delegating to an unregulated care provider (UCP) who has received specialized training. Operating room technicians are usually trained for this skill.

Procedure

STEPS

1. Prepare sterile field just before planned procedure. Supplies are to be used immediately.
2. Select clean work surface above waist level.
3. Assemble necessary equipment.
4. Check dates or labels on supplies for sterility of equipment.
5. Perform handwashing and hand hygiene thoroughly. Option: Procedure may be performed with gloves on.
6. Place pack containing sterile drape on work surface and open as described in Figure 32-4.
7. With fingertips of one hand, pick up folded top edge of sterile drape.
8. Gently lift drape up from its outer cover and let it unfold by itself without touching any object. Discard outer cover with your other hand.

Equipment

- Sterile drape
- Assorted sterile supplies

RATIONALE

- Prevents exposure of sterile field and supplies to air and contamination.
- A once-sterile object held below waist is considered contaminated.
- Preparation of equipment in advance prevents a break in the technique.
- Equipment stored beyond expiration date is considered unsterile.
- Reduces microbial counts on skin.
- Ensures sterility of packaged drape.
- The 2.5 cm border around drape is unsterile and may be touched with fingers or clean gloves.
- If sterile object touches any nonsterile object, it becomes contaminated.

► SKILL 32-2 Preparation of a Sterile Field—cont'd

9. With your other hand, grasp adjacent corner of drape and hold it straight up and away from your body (see Step 9 illustration).
10. Holding drape, first position and lay bottom half over intended work surface (see Step 10 illustration).

Step 9 Hold drape straight up and away from body.

11. Allow top half of drape to be placed over work surface last (see Step 11 illustration).
12. Grasp 2.5 cm border around edge to position as needed.

Adding Sterile Item

13. Open sterile item (according to package directions) while holding outside wrapper in nondominant hand.
14. Carefully peel wrapper onto nondominant hand. Do not shake item onto sterile field.
15. Being sure wrapper does not fall down on sterile field, place item onto field at angle. Do not hold arm over sterile field (see Step 15 illustration).

Step 11 Place top half of drape over work surface.

16. Dispose of outer wrapper.
17. Perform procedure using sterile technique.

- Drape can now be properly placed while using two hands. Drape must be held away from unsterile surfaces.
- Prevents you from reaching over sterile field.

Step 10 Lay bottom half of drape over work surface.

- Creates flat sterile work surface.
- Assists in differentiating and organizing the sterile surface.
- Frees dominant hand for unwrapping outer wrapper.
- Item remains sterile.
- Prevents reaching over field and contaminating its surface.

Step 15 Adding item to sterile field.

- Prevents accidental contamination of sterile field.
- Prevents transmission of infection to patient.

Recording and Reporting

- It is not necessary to record or report this procedure.

by carefully placing them directly on the field or by transferring them with a sterile forceps. A sterile object that comes in contact with the 2.5-cm border must be discarded.

You may choose to wear sterile gloves while preparing items on the field. If this is done, you can touch the entire drape, but sterile items must be handed over by an assistant. Your gloves cannot touch the wrappers of sterile items.

Pouring Sterile Solutions. Often you must pour sterile solutions into sterile containers. A bottle containing a sterile solution is sterile on the inside and contaminated on the outside; the outside neck of the bottle is also contaminated, but the inside of the bottle cap is considered sterile. After the cap or lid is removed, it is held in the hand or placed sterile side (inside) up on a clean surface. This means that the inside of the lid can be seen as it rests on the table surface. A bottle cap or lid should never rest on a sterile surface, even though the inside of the cap is sterile. The outer edge of the cap is unsterile and would contaminate the sterile surface. Likewise, placing a sterile cap down on an unsterile surface increases the chances of the inside of the cap becoming contaminated.

You need to check the label of the bottle to ensure it is the correct solution. Then hold the bottle with its label in the palm of the hand to prevent the possibility of the solution wetting and fading the label. Before pouring the solution into the container, pour a small amount (1 to 2 mL) into a disposable cap or plastic-lined waste receptacle. The discarded solution cleans the lip of the bottle. The edge of the bottle is kept away from the edge or inside of the receiving container. Pour the solution slowly to avoid splashing the underlying drape or field. The bottle should never be held so high above the container that even slow pouring will cause splashing. The bottle should be held outside the edge of the sterile field.

Surgical Scrub. Patients undergoing operative procedures are at an increased risk for infection. When working in operating rooms, you must perform surgical hand antisepsis to decrease and suppress the growth of skin microorganisms, in case your glove tears (Operating Room Nurses Association of Canada [ORNAC], 2003).

During surgical hand antisepsis before an operation, scrub from your fingertips to your elbows with an antiseptic soap. The optimum duration of the surgical hand scrub is unclear, although research indicates that it may be dependent on the type of antimicrobial product. Either an antimicrobial surgical scrub agent intended for surgical hand antisepsis or an alcohol-based antiseptic surgical hand rub that has persistent and cumulative activity is acceptable to use as a surgical scrub. For a traditional scrub, a three- to five-minute scrub should be performed to allow adequate contact time with the product, using the manufacturer's written instructions (Association of periOperative Registered Nurses [AORN], 2010; Meeker & Rothrock, 1999). You should follow your agency's policy for length of scrub time. A study by Gupta et al. (2007) suggested that neither a brush nor a sponge is necessary to reduce bacterial counts on the hands, especially when an alcohol-based product is used.

For maximum elimination of bacteria, all jewellery should be removed, including wristwatches, and the nails should be kept clean and short (AORN, 2010). Artificial nails should not be worn because they may harbour a greater number of bacteria. Similarly, nail polish should be avoided because it conceals soil under the nails and because chipped nail polish may increase the bacterial load (Health Canada, 2007). Freshly applied polish (not chipped or worn for more than four days) may be acceptable, if permitted by your facility's policy (CDC, 2007). If you have active skin infections, open lesions or cuts, or respiratory infections, you should be excluded from the surgical team. Skill 32-3 describes the steps for surgical hand hygiene.

Applying Sterile Gloves. Sterile gloves are an additional barrier to bacterial transfer. If you work on general nursing divisions, use *open gloving* before procedures such as dressing changes and urinary catheter insertions. *Closed gloving*, which is performed after you apply sterile gowns, is practised in operating rooms and special treatment areas. Skills 32-4 and 32-5 review the steps of each sterile gloving technique. The

Text continued on p. 659

► SKILL 32-3 Surgical Handwashing/Hand Hygiene: Preparing for Gowning

Delegation Considerations

The role of the scrub nurse can be delegated to a surgical technologist or licensed practical nurse. UCPs can help the registered nurse in the circulating nurse role by opening sterile supplies, setting up sterile fields, and running errands under the direction of the registered nurse.

Equipment

- Deep sink with foot or knee controls for dispensing water and soap (faucets should be high enough for hands and forearms to fit comfortably)
- Antimicrobial surgical scrub agent or alcohol-based waterless antiseptic, according to agency policy (product should be nonirritating, broad spectrum, fast acting, and effective in reducing skin microorganisms and have a residual effect) (Association of periOperative Registered Nurses [AORN], 2010; ORNAC, 2003)
- Surgical scrub sponge (if using traditional surgical hand scrub) and a disposable nail cleaner
- Paper mask and cap or hood
- Sterile towel
- Proper scrub attire
- Protective eyewear (glasses or goggles)

Procedure

STEPS

1. Consult your agency's policy regarding required length of scrub time and antiseptic to use for hand antisepsis.

RATIONALE

- Guidelines vary regarding ideal time needed and antiseptic to use for surgical scrub.

► SKILL 32-3 Surgical Handwashing/Hand Hygiene: Preparing for Gowning—cont'd

2. Be sure fingernails are short, clean, and healthy. Artificial nails should be removed. Natural nails should be less than 0.5 cm long.

- Long nails and chipped or old polish increase number of bacteria residing on nails. Long fingernails can puncture gloves, causing contamination. Artificial nails are known to harbour Gram-negative microorganisms and fungus (WHO, 2005).

Critical Decision Point: Remove nail polish if chipped or worn longer than four days because it may harbour microorganisms (AORN, 2004; ORNAC, 2003).

3. Inspect hands for presence of abrasions, cuts, or open lesions.

- These conditions increase the likelihood of microorganisms residing on skin surfaces.
- Mask prevents escape into air of microorganisms that can contaminate hands. Other protective wear prevents exposure to blood and body fluid splashes during the procedure.

5. Surgical handwashing:

A. Turn on water using knee or foot controls.

B. Wet hands and arms under running water and lather with detergent to 5 cm above elbows. (Hands need to be above elbows at all times.)

C. Rinse hands and arms thoroughly under running water.

Remember to keep hands above elbows.

D. Under running water, clean under nails of both hands with nail pick. Discard after use (see Step 5D illustration).

E. Wet clean sponge and apply antimicrobial detergent. Scrub nails of one hand with 15 strokes. Holding sponge perpendicular, scrub palm, each side of thumb and fingers, and posterior side of hand with 10 strokes each. The arm is mentally divided into thirds, and each third is scrubbed 10 times (see Step 5E illustrations). The duration of scrub is determined by the manufacturer's recommendations for the scrub agent used, which is usually 2 to 6 minutes (ORNAC, 2003). Rinse sponge and repeat sequence for other arm. A two-sponge method may be substituted. Check your agency's policy.

- Water runs by gravity from fingertips to elbows flowing from least to most contaminated areas. Hands become cleanest part of upper extremity. Washing a wide area reduces risk of contaminating overlying gown that you later apply.
- Rinsing removes transient bacteria from fingers hands and forearms.
- Removes dirt and organic material that harbour large numbers of microorganisms.
- Friction loosens resident bacteria that adhere to skin surfaces. Technique ensures coverage of all surfaces. Scrubbing is performed from cleanest area (hands) to marginal area (upper arms).

Step 5D Clean under fingernails.

A

B

Step 5E A, Scrub side of fingers. B, Scrub forearms.

Continued

► SKILL 32-3 Surgical Handwashing/Hand Hygiene: Preparing for Gowning—cont'd

- F. Discard sponge and rinse hands and arms thoroughly (see Step 5F illustration). Turn off water with foot or knee control and back into room entrance with hands elevated in front of and away from the body.

Step 5F Rinse arms.

- After touching skin, the sponge is considered contaminated. Rinsing removes resident bacteria. Using foot or knee tap control and backing into room prevents accidental contamination.

- G. Walk up to sterile tray and lean forward slightly to pick up a sterile towel (see Step 5G illustration). Dry one hand thoroughly, moving from fingers to elbow. Dry in a rotating motion. Dry from cleanest to least clean area (see Step 5G illustration).

- Drying prevents chapping and facilitates donning of gloves. Leaning forward prevents accidental contact of arms with scrub attire.

Step 5G A, Grasping sterile towel. B, Drying sequence.

- H. Repeat drying method for other hand by carefully reversing towel or using a new sterile towel.
- I. Discard towel.
- J. Proceed with sterile gowning (see Skill 32-4).
6. Alternative method of surgical hand hygiene using alcohol-based antiseptic:
- A. Wash hands with soap and water for at least 15 seconds to remove soil.
- B. Under running water, clean under nails of both hands with disposable nail cleaner. Discard after use and dry hands with paper towel.

- Prevents accidental contamination.
- Prevents accidental contamination.
- Removes dirt and organic material that harbour large numbers of microorganisms.

► SKILL 32-3 Surgical Handwashing/Hand Hygiene: Preparing for Gowning—cont'd

C. Apply enough alcohol-based waterless antiseptic to one palm to cover both hands thoroughly (see Step 6C illustration). Spread the antiseptic over all surfaces of the hands and fingernails. Follow product instructions for length of time to rub over hand surfaces. Allow to air-dry.

- Ensures coverage of all surfaces. Air-drying ensures complete antiseptics is achieved.

Step 6C Application of antimicrobial agent for brushless hand scrub. This nurse is using 3M Avagard. **Source:** Photo courtesy of 3M Health Care.

D. Repeat the process and allow hands to air-dry before applying sterile gloves.

Recording and Reporting

- It is not necessary to record or report this procedure.
- Report any dermatitis to employee health or infection control per your agency's policy.

► SKILL 32-4 Applying a Sterile Gown and Performing Closed Gloving

Delegation Considerations

The role of the scrub nurse can be delegated to a surgical technician.

Equipment

- Surgical cap
- Surgical mask
- Eyewear
- Foot covers
- Sterile gown (prepared by circulating nurse)

Procedure

STEPS

1. Before entering operating room or treatment area, apply cap, face mask, and eyewear. Foot covers are also required in operating room.
2. Perform thorough surgical hand hygiene (see Skill 32-3).
3. Ask circulating nurse to assist by opening sterile pack containing sterile gown (folded inside out).
4. Have circulating nurse prepare glove package by peeling outer wrapper open while keeping inner contents sterile. Inner glove package is then placed on sterile field created by sterile outer wrapper.
5. Reach down to sterile gown package; lift folded gown directly upward and step back away from table.
6. Holding folded gown, locate neckband. With both hands, grasp inside front of gown just below neckband.
7. Allow gown to unfold, keeping inside of gown toward body. Do not touch outside of gown with bare hands or allow it to touch the floor.

RATIONALE

- Prevent hair and air droplet nuclei from contaminating sterile work areas. Eyewear protects mucous membranes of eye. Foot covers are paper or cloth and fit over work shoes.
- Remove transient and resident bacteria from fingers hands and forearms.
- Gown's outer surface remains sterile.
- This action keeps gloves sterile and allows nurse who has scrubbed to handle sterile items.
- This action provides wide margin of safety, avoiding contamination of gown.
- Clean hands may touch inside of gown without contaminating outer surface.
- Outside of gown will remain sterile surface.

Continued

► SKILL 32-4 Applying a Sterile Gown and Performing Closed Gloving—cont'd

8. With hands at shoulder level, slip both arms into armholes simultaneously (see Step 8 illustration). Ask circulating nurse to bring gown over shoulders by reaching inside to arm seams and pulling gown on, leaving sleeves covering hands.
9. Have circulating nurse securely tie back of gown at neck and waist (see Step 9 illustration). (If gown is a wraparound style, sterile flap to cover gown is not touched until you have gloved.)

Step 8 Place arms in sleeves.

Step 9 Circulating nurse ties scrub gown.

10. Closed gloving:

- A. With hands covered by gown sleeves, open inner sterile glove package (see Step 10A illustration).
- B. With dominant hand inside gown cuff, pick up glove for nondominant hand by grasping folded cuff.
- C. Extend nondominant forearm with palm up and place palm of glove against palm of nondominant hand. Glove fingers will point toward elbow.
- D. Grasp back of glove cuff with covered dominant hand and turn glove cuff over end of nondominant hand and gown cuff (see Step 10D illustration).

- Hands remain clean. Sterile gown cuff will touch sterile glove surface.
- Sterile gown touches sterile glove.
- Position glove for application over cuffed hand, keeping glove sterile.
- Seal that is created by glove cuff over gown prevents exit of microorganisms over operative sterile field.

Step 10A Open glove package.

Step 10D Apply glove to left hand, keeping right hand inside cuff.

- E. Grasp top of glove and underlying gown sleeve with covered dominant hand. Carefully extend fingers into glove, being sure glove's cuff covers gown's cuff.

► SKILL 32-4 Applying a Sterile Gown and Performing Closed Gloving—cont'd

F. Glove dominant hand in same manner, reversing hands (see Step 10F illustration). Use gloved nondominant hand to pull on glove. Keep hand inside sleeve (see Step 10F illustration).

- Sterile object touches sterile object and therefore stays sterile. Touching the sterile sleeve with the sterile gloved hand allows the gloved hands to remain sterile.

Step 10F Apply second glove.

G. Be sure fingers are fully extended into both gloves.

11. For wraparound sterile gowns, take gloved hand and release fastener or ties in front of gown.
12. Hand tie to sterile team member, who stands still (see Step 12 illustration). Allowing margin of safety, turn around to the left, covering back with extended gown flap. Take back tie from team member and secure tie to gown.

- Ensure that you have full dexterity while using gloved hand.
- Front of gown is sterile.
- Contact with team member could contaminate gown and gloves. Gown must enclose undergarments.

Step 12 Hand tie to sterile team member.

Recording and Reporting

- It is not necessary to record or report this procedure.

► SKILL 32-5 Open Gloving

video

Delegation Considerations

Delegation of open gloving depends on whether a UCP has received special training and is competent to perform the sterile procedure.

Procedure

STEPS

1. Perform thorough handwashing and hand hygiene.
2. Remove outer glove package wrapper by carefully separating and peeling apart sides.

Equipment

- Sterile gloves (proper size)

RATIONALE

- Removes bacteria from skin surfaces and reduces risk of transmitting infection.
- Prevents inner glove package from accidentally opening and touching contaminated objects.

Continued

► SKILL 32-5 Open Gloving—cont'd

video

3. Grasp inner package and lay it on clean, dry, flat surface just above waist level. Open package, keeping gloves on wrapper's inside surface (see Step 3 illustration).

Step 3 Open package.

4. If gloves are not prepowdered, take packet of powder and apply lightly to hands over sink or wastebasket.
5. Identify right and left gloves. Each glove has cuff approximately 5 cm wide. Glove dominant hand first.
6. With thumb and first two fingers of nondominant hand, grasp edge of cuff of glove for dominant hand. Touch only glove's inside surface.
7. Carefully pull glove over dominant hand, being sure cuff does not roll up wrist. Be sure thumb and fingers are in proper spaces (see Step 7 illustration).
8. With gloved dominant hand, slip fingers underneath second glove's cuff (see Step 8 illustration).

Step 7 Pull glove over dominant hand.

9. Carefully pull second glove over nondominant hand. Do not allow fingers and thumb of gloved dominant hand to touch any part of exposed nondominant hand. Keep thumb of dominant hand abducted back (see Step 9 illustration).

- Sterile object held below waist is contaminated. Inner surface of glove package is sterile.

- Powder allows gloves to slip on easily. (Some staff members do not use powder for fear of promoting growth of microorganisms.)
- Proper identification of gloves prevents contamination by improper fit. Gloving of dominant hand first improves dexterity.
- Inner edge of cuff will lie against skin and is thus not sterile.
- If glove's outer surface touches hand or wrist, then it is contaminated.
- Cuff protects gloved fingers. Sterile surface touching sterile surface prevents glove contamination.

Step 8 Slip fingers underneath second glove's cuff.

- Contact of gloved hand with exposed hand results in contamination.

► SKILL 32-5 Open Gloving—cont'd

10. After second glove is on, interlock hands. The cuffs usually fall down after application. Be sure to touch only sterile sides (see Step 10 illustration).

Step 9 Pull second glove over nondominant hand.

Glove Disposal

11. Grasp outside of one cuff with other gloved hand; avoid touching wrist.
12. Pull glove off, turning it inside out. Discard in receptacle.
13. Take fingers of bare hand and tuck inside remaining glove cuff. Peel glove off, inside out. Discard in receptacle. Perform hand hygiene.

Recording and Reporting

- It is not necessary to record or report this procedure.

- Ensure smooth fit over fingers.

Step 10 Interlock hands. Gloved hands must be kept above waist level within the visual field at all times or clasped together above elbow level.

- Minimize contamination of underlying skin.
- Outside of glove does not touch skin surface.

proper glove size should be selected; the glove should not stretch so tightly that it can easily tear, yet it should be tight enough that objects can be picked up easily.

Donning a Sterile Gown. You must wear a sterile gown when assisting at the sterile field in an operating room, delivery room, or special treatment areas so that sterile objects can be comfortably handled with less risk of contamination. If you are the circulating nurse, you do not usually wear a sterile gown. The sterile gown acts as a barrier to decrease the shedding of microorganisms from skin surfaces into the air, thus preventing wound contamination. You may also wear a sterile gown if you are caring for a patient with a large open wound or assisting a physician during a major invasive procedure (e.g., inserting an arterial catheter).

After you have applied a mask and surgical cap and performed surgical handwashing, you apply a sterile gown. Pick up the gown from a sterile pack, or ask an assistant to hand the gown to you. Only a certain portion of the gown—the area from the anterior waist to, but not including, the collar and the anterior surface of the sleeves—is considered sterile. The back of the gown, the area under the arms, the collar, the area below the waist, and the underside of the sleeves are not sterile because you cannot keep these areas in constant view and ensure their sterility. Skill 32-4 reviews the steps for applying a sterile gown and closed gloving, and Skill 32-5 reviews the method of open gloving.

❖Evaluation

Your success when practising infection control techniques is measured by determining whether the goals for reducing

or preventing infection are achieved. By comparing the patient's response, such as the absence of fever or development of wound drainage, with expected outcomes, you determine the success of nursing interventions. Similarly, you determine whether interventions should be revised or eliminated. Correctly assessing wounds for healing and conducting a physical assessment of body systems (see Chapter 31) are important skills in evaluation. You need to closely monitor patients, especially those at risk, for signs and symptoms of infection. For example, a patient who has undergone a surgical procedure is at risk for infection at the surgical site, as well as at sites of invasive procedures such as a venipuncture or central line insertion. In addition, the patient is at risk for a respiratory tract infection as a result of decreased mobility and for a urinary tract infection if an in-dwelling catheter is present. You must closely monitor all invasive and surgical sites for swelling, erythema, and purulent drainage. Breath sounds are monitored for changes, and sputum character is checked for purulence. Laboratory test results are reviewed for leukocytes in the urine, which may indicate a urinary tract infection. The absence of signs or symptoms of infection is the expected outcome of infection prevention and monitoring activities.

The patient at risk for infection must understand the measures needed to reduce or prevent microorganism growth and spread. Providing patients or family members with the opportunity to discuss infection control measures and to demonstrate procedures will increase their ability to comply with therapy. You may determine that patients require new information or that previously instructed information needs reinforcement.

You need to document the patient's response to therapies for infection control. A clear description of any signs and symptoms of systemic or local infection is necessary to give all nurses a baseline for comparative evaluation. The efficacy of any intervention in reducing infection must be reported.

❖ KEY CONCEPTS

- Hand hygiene is the most important technique to use in preventing and controlling the transmission of infection.
- The potential for microorganisms to cause disease depends on the number of organisms, their virulence, their ability to enter and survive in a host, and the susceptibility of the host.
- Normal body flora help to resist infection by releasing antibacterial substances and inhibiting the multiplication of pathogenic microorganisms.
- The signs of local inflammation and infection are identical.
- An infection can develop as long as the six elements making up the chain of infection are uninterrupted.
- Microorganisms are transmitted by direct and indirect contact, droplets, airborne particles, and contaminated vehicles and vectors.
- Advancing age, poor nutrition, stress, diseases of the immune system, chronic disease, and treatments or conditions that compromise the immune response increase a person's susceptibility to infection.
- The major sites for HAI are the urinary and respiratory tracts, the bloodstream, and surgical or traumatic wounds.
- The CDC now recommends the use of alcohol-based waterless antiseptics as an alternative to handwashing to more effectively reduce the transmission of pathogens.
- Invasive procedures, medical therapies, long hospitalization, and contact with health care personnel increase a hospitalized patient's risk for acquiring an HAI.
- Isolation practices may prevent personnel and patients from acquiring infections and may prevent the transmission of microorganisms.
- Standard precautions or routine practices entail the use of generic barrier techniques in the care of all patients.
- Transmission-based (isolation) precautions are used for patients with specific, highly transmissible infections.
- Proper cleansing necessitates the mechanical removal of soil from an object or area.
- A patient in isolation is subject to sensory deprivation because of the restricted environment.
- An infection control professional monitors the incidence of infection within an institution and provides educational and consultative services to maintain infection prevention.
- Surgical asepsis necessitates more stringent techniques than does medical asepsis and is directed at eliminating all microorganisms.
- Surgical aseptic practices are followed if the skin is broken or if you perform an invasive procedure in a body cavity that is normally free of microorganisms.

❖ CRITICAL THINKING EXERCISES

1. Mrs. Jaycock had an in-dwelling urethral catheter for one week. The catheter has now been out for 24 hours. She complains of frequency of and pain on urination. Mrs. Jaycock suggests that the catheter be re-inserted so that she does not need to get up frequently. What can frequency of or

pain on urination indicate? Should the catheter be re-inserted? Why or why not? Describe at least one appropriate assessment measure and independent nursing action for Mrs. Jaycock.

2. You are caring for Mr. Huang, who has a large, open, draining abdominal wound. You notice another health care worker changing Mr. Huang's dressing without wearing gloves or using sterile supplies or sterile technique. When you question the health care worker regarding this practice, the person says, "Don't worry, the wound is already infected, and the antibiotics and draining will take care of any contaminants." How would you respond to this comment? What would your next steps be in following up on this incident?
3. Mrs. Niles is 83 years of age and lives alone. She has difficulty walking and relies on a church volunteer group to deliver lunches during the week. Her fixed income limits her ability to buy food. Last week, Mrs. Niles's 79-year-old sister died. The two sisters had been very close. Explain the factors that might increase Mrs. Niles's risk for infection.
4. Mr. Vargas is admitted to your facility with a history of recent weight loss, a cough that has persisted for two months, and hemoptysis. His chest X-ray film shows a cavity in one lung, and his physician suspects tuberculosis. What type of isolation precautions would you use for Mr. Vargas? What protection would you use when providing care? What education would you provide for the patient and his family?

❖ REVIEW QUESTIONS

1. If an infection can be transmitted from one person to another, it is a
 1. Communicable disease
 2. Portal of entry to a host
 3. Portal of exit from a reservoir
 4. Susceptible host
2. The mode of transmission for hepatitis A is
 1. Direct and indirect contact
 2. Droplet transmission
 3. Airborne transmission
 4. Vectorborne transmission
3. The interval when a patient manifests signs and symptoms specific to a type of infection is the
 1. Incubation period
 2. Convalescence stage
 3. Prodromal stage
 4. Illness stage
4. The most important and basic way to break the chain of infection is by
 1. Wearing gloves
 2. Practising hand hygiene
 3. Placing patients in isolation
 4. Providing private rooms for patients
5. The minimum handwashing time necessary to remove most transient microorganisms is
 1. 1.5 seconds
 2. 15 seconds
 3. 60 seconds
 4. 3 minutes

6. A patient is on isolation precautions for pulmonary tuberculosis. You note that the patient seems to be angry, but you know this is a normal response to isolation. Your best intervention is to
 1. Provide a dark, quiet room to calm the patient
 2. Explain the isolation procedures and provide meaningful stimulation
 3. Reduce the level of precautions to keep the patient from becoming angry
 4. Limit family and other caregiver visits to reduce the risk of spreading the infection
7. A gown should be worn when
 1. The patient's hygiene is poor
 2. The patient has AIDS or hepatitis
 3. You are assisting with medication administration
 4. Blood or body fluids may get on your clothing from a task you plan to perform
8. You have dressed a patient's wound and now plan to administer a medication (which is currently in the room) to the patient. It is important to
 1. Remove your gloves and perform hand hygiene before leaving the room
 2. Remove your gloves and perform hand hygiene before administering the medication
 3. Leave your gloves on to administer the medication
 4. Leave the medication on the bedside table to avoid having to remove your gloves before leaving the patient's room
9. A patient on your unit develops diarrhea, which is confirmed to be caused by *C. difficile*. What type of isolation should this patient be placed on?
 1. Airborne isolation
 2. Contact precautions
 3. Standard precautions or routine practices
 4. Droplet precautions
10. When performing surgical hand hygiene, your hands must be kept
 1. Above your elbows
 2. Below your elbows
 3. At a 45-degree angle
 4. In a comfortable position

Medication Administration

Written by Sharon Kaasalainen, RN, PhD

Based on the original chapter by Amy M. Hall, RN, BSN, MS, PhD, CNE

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Examine the nurse's role and responsibilities regarding medication administration.
- Describe the physiological mechanisms of medication action, including absorption, distribution, metabolism, and excretion of medications.
- Differentiate among different types of medication actions.
- Discuss developmental factors that influence pharmacokinetics.
- Discuss factors that influence medication actions.
- Discuss methods of educating a patient about prescribed medications.
- Compare and contrast the roles of the physician, the pharmacist, and the nurse in medication administration.
- Implement nursing actions to prevent medication errors.
- Describe factors to consider when choosing routes of medication administration.
- Calculate a prescribed medication dose.
- Discuss factors to use when assessing a patient's needs for and response to medication therapy.
- Explain the 10 rights of medication administration.
- Prepare and administer subcutaneous, intramuscular, and intradermal injections; intravenous medications; hypodermoclysis infusions; oral and topical skin preparations; eye, ear, and nose drops; vaginal instillations; rectal suppositories; and inhalants.
- Describe the importance of safe medication techniques.
- Describe the importance of establishing and adhering to agency policies and procedures when administering medications.
- Identify and describe how principles of primary health care are applied to medication administration in nursing practice.

Patients who have acute or chronic diseases or conditions use a variety of strategies to restore or maintain their health. A medication is a substance used in the prevention, diagnosis, relief, treatment, or cure of health alterations. Medications are a primary treatment that patients associate with restoration of health. No matter where patients receive their health care—in hospitals, at clinics, or at home—nurses play an essential role in preparing and administering medications, teaching patients about medications, and evaluating patients' responses to medications. In the primary health care setting, patients often self-administer their medications. As a nurse, you are responsible for evaluating the effects of the medications on the patient's health status, teaching patients about their medications and their side effects, promoting patient adherence to the medication regimen, and evaluating the patient's technique for all routes of medication delivery. Additionally, you must assess the relationship between a patient's medication regime and socioenvironmental influences, including accessibility to resources (e.g., financial and geographical). Consistent with principles of primary health care, nurses can implement interventions to address barriers to effective medication management.

In both acute and restorative health care settings, nurses spend a great deal of time administering medications to patients and ensuring that patients are adequately prepared to self-administer medications when they are discharged. If patients cannot administer their own medications when they are at home, family members or support persons can take responsibility for this task. As a nurse, you assess the effect of the medications in restoring or maintaining health and continue to educate the patient, the patient's family, and home care personnel about the medication's purpose, regimen, and side effects.

Scientific Knowledge Base

Medications are administered to patients to prevent, diagnose, or treat disease and health conditions. Because medication administration and evaluation are essential to nursing practice, you need to understand the actions and effects of the medications your patients take. To safely and accurately administer medications, you must have an understanding of pharmacology, pharmacokinetics (the study of how medications enter, affect, and exit the body), human growth and development, human anatomy, pathophysiology, psychology, nutrition, and mathematics. You need to apply your cumulative nursing knowledge when administering medications. The nursing process provides the framework for you to organize your thoughts and actions, and it is the foundation for medication administration.

Pharmacological Concepts

Drug Names. A medication may have as many as three different names. A medication's chemical name provides an exact description of the medication's composition and molecular structure. Chemical names are rarely used in clinical practice. For example, the chemical name N-acetyl-para-aminophenol is commonly known as Tylenol. The generic, or nonproprietary, name is given by the manufacturer that first develops the medication. Acetaminophen is the generic name for Tylenol. The generic name becomes the official name under which the medication is listed in official publications, such as the *Compendium of Pharmaceuticals and Specialties (CPS)*, the

Canadian Formulary (CF), or the *United States Pharmacopeia (USP)*. In addition to the drug name, all drug products approved for distribution in Canada have an eight-digit number, which is assigned by the Health Protection Branch of the federal government. This Drug Identification Number (DIN) is used by various groups and agencies to track drug information across Canada.

The trade name, brand name, or proprietary name is the name under which a manufacturer markets a medication. The trade name is followed by the symbol TM, which indicates that the manufacturer has trademarked the medication's name (e.g., TemptraTM, MotrinTM). Manufacturers choose trade names that are easy to pronounce, spell, and remember so that laypersons will remember the medication names. A medication may be produced by many different companies, and similarities in their trade names can be confusing. Because similarities in drug names are a common cause of medical errors, the Joint Commission (2007) in the United States publishes on its Web site a list of drugs whose names look like or sound like other drug names as well as recommendations for nurses, prescribers, other health care providers, and health care organizations to prevent drug errors related to look-alike and sound-alike names of medications. Medications are available under a variety of different nomenclatures, or names, and you must be careful to obtain the exact name and spelling for the particular medications you administer.

Classification. Medication classification indicates the effect of the medication on a body system, the symptoms the medication relieves, or the medication's desired effect. For example, patients who have type 2 diabetes often take medications to control their blood glucose level. *Sulfonylureas* are one classification of medications often used by these patients. At least seven different medications are included in the sulfonylurea classification (McKenry et al., 2006). A prescriber chooses a particular medication on the basis of the patient's characteristics; the medication's cost, efficacy, and dosing frequency; and the prescriber's experience with the medication. Some medications belong to more than one class. For example, aspirin is an analgesic, an antipyretic, and an anti-inflammatory medication.

Medication Forms. Medications are available in a variety of forms, or preparations (Figure 33-1). The form of the medication determines its route of administration. The composition of a medication is designed to enhance its absorption

Figure 33-1 Forms of oral medications. Top row: Uniquely shaped tablet, capsule, scored tablet. Bottom row: Gelatin-coated liquid, extended-release capsule, enteric-coated tablet.

and metabolism. Many medications are made in several forms, such as tablets, capsules, elixirs, and suppositories. When administering a medication, you must be certain to use the proper form (Table 33-1).

Medication Legislation and Standards

Canadian Drug Legislation. Regulation of drug standards began in Canada in 1884, when the *Adulteration Act* set the conditions under which a drug could be adulterated. The *Food and Drugs Act* of 1920 replaced this Act and, with amendments in 1950, gave the federal government control of the manufacture and sale of all drugs (except narcotics), all food, all cosmetics, and certain medical devices.

The federal government first attempted to control narcotic substances in 1908 through the *Opium Act*. Cocaine and morphine came under the jurisdiction of this Act in 1911. In 1961, the *Narcotic Control Act*, which controls the manufacture, distribution, and sale of narcotic drugs, was enacted. This Act was repealed in 1996 and replaced by the *Controlled Drugs and Substances Act*. The federal government has also passed legislation that regulates the manufacture and sale of herbs and other natural health products. This legislation addresses the content of these products as well as the products' packaging, labelling, distribution, and storage.

Drug Standards. Official publications, such as the *British Pharmacopoeia (BP)* and the *Canadian Formulary*, set standards

► TABLE 33-1 Forms of Medication

Form	Description
Medication Forms Commonly Prepared for Administration by Oral Route	
Solid Forms	
Caplet	Shaped like a capsule and coated for ease of swallowing.
Capsule	Medication encased in a gelatin shell.
Tablet	Powdered medication compressed into a hard disc or cylinder; in addition to primary medication, contains binders (adhesives that allow the powder to stick together), disintegrators (to promote tablet dissolution), lubricants (for ease of manufacturing), and fillers (to make a convenient size for swallowing).
Enteric-coated tablet	Coated tablet that does not dissolve in stomach; coatings dissolve in intestine, where medication is absorbed.
Pill	Contains one or more medications; shaped into globules, ovoids, or oblongs; rarely used because most pills have been replaced by tablets.
Liquid Forms	
Elixir	Clear fluid containing medication and either water or alcohol, or both; often sweetened.
Extract	Syrup or dried form of pharmacologically active medication, usually made by evaporating the solution.
Aqueous solution	Medication dissolved in water.
Aqueous suspension	Finely divided drug particles dispersed in a liquid medium; when the suspension is left standing, particles settle to the bottom of the container.
Syrup	Medication dissolved in a concentrated sugar solution.
Tincture	Medicinal alcoholic extract from a plant or vegetable.
Other Oral Forms and Terms Associated With Oral Preparations	
Troche (lozenge)	Flat, round tablet that dissolves in the mouth to release medication; not intended for ingestion.
Aerosol	Aqueous medication sprayed and absorbed in the mouth and upper airway; not intended for ingestion.
Sustained release	Tablet or capsule that contains small particles of a medication coated with material that requires time to dissolve.
Medication Forms Commonly Prepared for Administration by Topical Route	
Ointment (salve or cream)	Semisolid, externally applied preparation, usually containing one or more medications.
Liniment	Preparation that usually contains medication and alcohol, oil, or soapy emollient; applied to the skin.
Lotion	Liquid suspension that usually protects, cools, or cleanses skin and can contain medication.
Paste	Thick ointment; absorbed through the skin more slowly than ointment; often used for skin protection.
Transdermal disc or patch	A disc or patch from which medication is absorbed through the skin slowly over a long period of time (e.g., 24 hours, 1 week).
Medication Forms Commonly Prepared for Administration by Parenteral Route	
Solution	Sterile preparation that contains water with one or more dissolved medicinal compounds.
Powder	Sterile particles of medication that are dissolved in a sterile liquid (e.g., water or normal saline) before administration.
Medication Forms Commonly Prepared for Instillation Into Body Cavities	
Solution	Medication dissolved in water or other liquid.
Intraocular disc	Small, flexible oval (similar to a contact lens) consisting of two soft, outer layers and a middle layer containing medication; slowly releases medication when moistened by ocular fluid.
Suppository	Solid medicine dosage mixed with gelatin and shaped into a pellet for insertion into a body cavity (rectum or vagina); melts at body temperature to release medication.

for drug strength, quality, purity, packaging, safety, labelling, and dosage form. Physicians, nurses, and pharmacists depend on these standards to ensure that patients receive pure drugs in safe and effective dosages.

Accepted standards must be met in the following areas:

- **Purity:** Manufacturers must meet purity standards for the type and concentration of substances allowed in drug products.
- **Potency:** The concentration of the active drug in the preparation affects its strength, or potency.
- **Bioavailability:** The ability of a drug to be released from its dosage form and to be dissolved, absorbed, and transported by the body to the drug's site of action.
- **Efficacy:** Detailed laboratory studies help determine a drug's effectiveness.
- **Safety:** All drugs need to be continually evaluated to determine their side effects.

Control. Administration of the *Food and Drugs Act* and the *Controlled Drugs and Substances Act* is carried out by the Health Protection Branch (HPB) of the federal government. Before a new drug can be marketed in Canada, an application for approval must be made to the HPB. After intensive testing to ensure the drug's effectiveness and safety in humans, the HPB reviews the application. The HPB issues a Drug Identification Number and Notification of Compliance, which allow the drug to be sold in Canada. Stringent controls are applied to this new drug until sufficient information has been accumulated to ensure its safety and efficacy. Only then is the drug released for general use. Monitoring of the drug is ongoing to report adverse effects, safety concerns, or changes in the indications for a particular drug's use.

Provincial, Territorial, and Local Regulation of Medication. The provincial and territorial governments do not directly regulate the manufacture or sale of drugs. However, because the provincial and territorial governments have most of the legislative responsibility for health care, provincial and territorial legislation indirectly affects the use and sale of drugs within provincial and territorial boundaries. In addition, each province and territory has legislation regarding medical, dental, pharmacy, and nursing practice that dictates each health care provider's role in the ordering, dispensing, and administration of drugs. In particular, some provincial and territorial pharmacy legislation includes schedules that indicate the drugs that can be sold without prescription, over the counter, and by prescription only. The National Association of Pharmacy Regulatory Authorities facilitates the activities of the regulatory authorities of all provinces and Yukon and promotes the harmonization of the practice of drug sales across the country.

Health care institutions establish policies that conform to federal and provincial regulations. The size of an institution, the types of services it provides, and the types of professional personnel it employs influence an institution's policies for drug control, distribution, and administration. Because an institution is primarily concerned with preventing health problems resulting from drug use, institutional policies are often more restrictive than government controls. For example, a common institutional policy is the automatic discontinuation of antibiotic therapy after a predetermined number of days. Although a prescriber may reorder an antibiotic, this policy helps to control unnecessarily prolonged drug therapy, which may lead to drug sensitivity or toxic reactions.

Medication Regulation and Nursing Practice. In Canada, you must be familiar with both the federal and

provincial or territorial regulations affecting drug administration in your practice areas. If you move from one province or territory to another, you may discover significant differences in the laws governing drug administration. For example, laws vary concerning the prescription and administration of drugs. In the past, only physicians could prescribe medications. Today, most provinces have amended their nursing practice acts to include the prescription of medications by nurses in advanced practice. In most cases, this privilege is limited to nurse practitioners, clinical nurse specialists, and nurse midwives.

Provincial nursing organizations have developed regulations that guide nursing practice with regard to medication administration; for example, the College of Nurses of Ontario *Practice Standard on Medication* (2008), the College and Association of Registered Nurses of Alberta *Medication Administration Guidelines for Registered Nurses* (2007), and the Saskatchewan Registered Nurses' Association *Medication Administration Guidelines for Registered Nurses* (2007). Such guidelines are intended to promote safe medication administration practices for nurses.

You are responsible for following legal provisions when administering **controlled substances** (drugs that affect the mind or behaviour), which can be dispensed only with a prescription. Violations of the *Narcotic Control Act* are punishable by fines, imprisonment, and loss of your nursing licence or your nursing registration. Hospitals and other health care institutions have policies for the proper storage and distribution of controlled substances, including narcotics (Box 33-1). **Narcotics** are natural opioid drugs or semi-synthetic or synthetic substitutes for these drugs.

► BOX 33-1

Guidelines for Safe Narcotic Administration and Control

- Store all narcotics in a locked, secure cabinet or container. (Cabinets with computer-controlled locking devices are preferred.)
- Count narcotics frequently. Count and record inventories on a continuous basis, especially when narcotic drawers are opened and when nursing shifts change.
- Report discrepancies in narcotic counts immediately.
- Use a special inventory record each time a narcotic is dispensed. Records are often kept electronically and provide an accurate ongoing count of narcotics used, narcotics remaining, and information about narcotics that are wasted.
- After dispensing a narcotic, use the record to document the patient's name, the date and time of medication administration, the name of the medication, the dose, and your signature.
- If you dispense only part of a premeasured dose of a controlled substance, a second nurse must witness disposal of the unused portion. If paper records are kept, both you and the nurse who witnesses the wastage are required to sign the form. Computerized systems record the nurses' names electronically. Do not place wasted portions in the sharps containers. Instead, flush wasted portions of tablets down a toilet and wash wasted liquids down a sink or return to the pharmacy, depending on your institution's policy for disposal of wasted controlled substances.

Pharmacokinetics as the Basis of Medication Actions

For medications to be therapeutic, they must be taken into a patient's body, where they are absorbed and distributed to cells, tissues, or a specific organ, and they must alter physiological functions. **Pharmacokinetics** is the study of how medications enter the body, reach their site of action, metabolize, and exit the body. Use your knowledge of pharmacokinetics when timing medication administration, selecting the route of administration, considering the patient's risk for alterations in medication action, and evaluating the patient's response.

Absorption. Absorption refers to the passage of medication molecules into the blood from the medication's site of administration. Medication absorption is affected by the route of administration, the ability of the medication to dissolve, blood flow to the site of administration, the patient's body surface area, and lipid solubility (maximum concentration of a chemical that will dissolve in fatty substances) of medication.

Route of Administration. Each route of medication administration has a different rate of absorption. When medications are applied to the skin, absorption is slow due to the physical makeup of the skin. Medications placed on the mucous membranes and respiratory airways are quickly absorbed because these tissues are highly vascular. Because orally administered medications must pass through the gastrointestinal (GI) tract to be absorbed, the overall rate of absorption is usually slow. Intravenous (IV) injection produces the most rapid absorption because this route provides immediate access to systemic circulation.

Ability of the Medication to Dissolve. The ability of an oral medication to dissolve depends on its form or preparation. Solutions and suspensions in a liquid state are absorbed more readily than tablets or capsules. Acidic medications pass through the gastric mucosa rapidly. Medications that have a base pH are not absorbed before reaching the small intestine.

Blood Flow to the Site of Administration. When the site of administration contains a rich blood supply, the body absorbs medications more rapidly. As blood comes in contact with the site of administration, the medication is absorbed. Therefore, areas that have more blood supply will experience enhanced absorption, facilitating the passage of the medication into the bloodstream.

Body Surface Area. When a medication is in contact with a large surface area, the medication will be absorbed at a faster rate. This characteristic explains why most medications are absorbed in the small intestine, not in the stomach.

Lipid Solubility of a Medication. Because the cell membrane has a lipid layer, highly lipid-soluble medications easily cross the cell membrane and are absorbed quickly. The absorption of medication is also affected by the presence of food in the stomach. Some oral medications are absorbed more easily when administered between meals or on an empty stomach because food can change the structure of a medication and impair its absorption. When you administer medications, you should be aware of potential medication-medication interactions listed in the *CPS*, in drug manuals, and on drug packaging. If medications that interact are ordered at the same time, notify the prescriber immediately to revise medication administration times.

Safe medication administration requires knowledge of factors that may alter or impair the absorption of the prescribed medications. This information is based on an

understanding of the medication's pharmacokinetics, the patient's history, the physical examination of the patient, and knowledge gained through daily interactions with patients. Use this knowledge to ensure that you administer all prescribed medications at the correct time. Consult and collaborate with the patient's prescribers to ensure the patient achieves the therapeutic effect of all medications. Before administering any medication, check pharmacology books or drug references and package inserts, or consult with pharmacists to identify medication-medication interactions or medication-nutrient interactions. Furthermore, because the safe delivery of many medications (e.g., blood pressure-lowering agents, blood glucose-lowering medications, and anti-arrhythmics) is dependent on nursing assessments, ensure that physical assessment data are collected and interpreted before administering medications.

Distribution. After a medication is absorbed by the body, it is distributed to tissues and organs and to its specific site of action. The rate and extent of distribution depend on the physical and chemical properties of the medications and the physiology of the person taking the medication.

Circulation. After a medication enters the bloodstream, it is carried throughout the body's tissues and organs. The speed at which it reaches the site depends on the vascular content of the tissues and organs. Conditions that limit blood flow or blood perfusion inhibit the distribution of a medication. For example, patients who have experienced heart failure have impaired circulation, which also impairs medication delivery to the intended site of action. Therefore, the efficacy of medications in heart failure patients can be delayed or altered.

Membrane Permeability. For a medication to be distributed to an organ, it must pass through all the organ's tissues and biological membranes. Some membranes serve as barriers to the passage of medications. For example, the blood-brain barrier allows only fat-soluble medications to pass into the brain and cerebral spinal fluid. Therefore, central nervous system infections require treatment with antibiotics that selectively cross the blood-brain barrier. This change in the permeability of the blood-brain barrier can lead to confusion and other adverse effects in some older patients. The placental membrane also has a nonselective barrier to medications. Fat-soluble and non-fat-soluble agents can cross the placenta and result in fetal deformities, respiratory depression, and, when combined with narcotic use, withdrawal symptoms.

Protein Binding. Most medications bind to proteins to some extent. The degree to which medications bind to serum proteins, such as albumin, affects the medication's distribution. Medications bound to albumin cannot exert pharmacological activity. The unbound, or free, medication is the active form of the medication. Older adults have a decrease in albumin in their bloodstream, which is probably the result of a change in their liver function. The same is true for patients who have liver disease or malnutrition, who, along with older adults, have the potential for more medication being unbound, and thus may be at risk for an increase in medication activity or toxicity, or both.

Metabolism. After a medication reaches its site of action, it metabolizes into a less active or inactive form that is more easily excreted. **Biotransformation** occurs when enzymes **detoxify**, degrade (break down), and remove the biologically active chemicals. Most biotransformation occurs within the liver, although the lungs, kidneys, blood, and intestines also metabolize medications. The liver is especially important

because its specialized structure oxidizes and transforms many toxic substances. The liver degrades many harmful chemicals before they are distributed to the tissues. If a decrease in liver function occurs, a medication is usually eliminated more slowly and results in an accumulation of the medication. If the organs that metabolize medications are altered, patients are at risk for medication toxicity. For example, a small sedative dose of a barbiturate may cause a patient with liver disease to lapse into a hepatic coma.

Excretion. After medications are metabolized, they exit the body through the kidneys, liver, bowel, lungs, or exocrine glands. The chemical makeup of a medication determines the organ of excretion. Gaseous and volatile compounds, such as nitrous oxide and alcohol, exit through the lungs. Deep breathing and coughing (see Chapter 48) help the postoperative patient to eliminate anaesthetic gases more rapidly. The exocrine glands excrete lipid-soluble medications. When medications exit through the sweat glands, the skin often becomes irritated. You can assist the patient in good hygiene practices (see Chapter 37) to promote cleanliness and skin integrity. If a medication is excreted through the mammary glands, a nursing infant is at risk of ingesting the chemicals. You will need to check on the safety of any medication used by breastfeeding women.

The GI tract is another route for medication excretion. Many medications enter the hepatic circulation where they are broken down by the liver and excreted into the bile. After chemicals enter the intestines through the biliary tract, they may be reabsorbed by the intestines. Factors that increase peristalsis (e.g., laxatives and enemas) accelerate medication excretion through the feces, whereas factors that slow peristalsis (e.g., inactivity and improper diet) may prolong a medication's effects.

The kidneys are the main organs for medication excretion. Some medications escape extensive metabolism and exit unchanged in the urine. Other medications must undergo biotransformation in the liver before being excreted by the kidneys. If renal function declines, a patient is at risk for medication toxicity. If the kidneys cannot adequately excrete a medication, the dose may need to be reduced. Maintenance of an adequate fluid intake (50 mL/kg/day) promotes proper elimination of medications for the average adult.

Types of Medication Action

Medications vary considerably in the way they act and in their types of action. Factors other than characteristics of the medication also influence medication actions. A patient does not always respond in the same way to each successive dose of a medication. Sometimes, the same medication causes very different responses in different patients. Therefore, you need to understand all the effects that medications can have on patients.

Therapeutic Effects. The therapeutic effect is the expected or predictable physiological response that a medication causes. Each medication has a desired therapeutic effect, which is the reason it is prescribed. For example, nitroglycerine reduces the body's cardiac workload and increases myocardial oxygen supply. A single medication may have more than one therapeutic effect. For example, aspirin reduces platelet aggregation (clumping) and is an analgesic, an antipyretic, and an anti-inflammatory drug. Knowing the desired therapeutic effect for each medication allows you to provide patient education to accurately evaluate the medication's desired effect.

Side Effects. Side effects are the unintended, secondary effects that a medication predictably will cause. Side effects may be harmless or injurious. If the side effects are serious enough to negate a medication's intended beneficial effects, the prescriber may decide to discontinue the medication. Patients often stop taking medications because of side effects.

Adverse Effects. Adverse effects are severe, negative responses to medication. For example, a patient may become comatose after ingesting a drug. When adverse responses to medications occur, the prescriber immediately discontinues the medication. Some adverse effects are unexpected effects that were not discovered during drug testing. When this situation occurs, health care providers should report the adverse effect to the Health Protection Branch of the federal government (<http://www.hc-sc.gc.ca/dhp-mps/medeff/report-declaration/index-eng.php#a2>). This reporting system is voluntary.

Toxic Effects. Toxic effects develop after prolonged intake of a medication or after a medication accumulates in the blood because of impaired metabolism or impaired excretion. Excess amounts of a medication within the body may have lethal effects, depending on the medication's action. For example, toxic levels of morphine, which is an opioid, may cause severe respiratory depression and death. Antidotes are available to treat specific types of medication toxicity. For example, Narcan is used to reverse the effects of opioid toxicity.

Idiosyncratic Reactions. Medications sometimes cause unpredictable effects, such as an **idiosyncratic reaction**, which occurs when a patient overreacts or underreacts to a medication or has a reaction different from the normal reaction. For example, a child receiving an antihistamine (Benadryl) may become extremely agitated or excited instead of becoming drowsy. It is not always possible to predict whether a patient will have an idiosyncratic response to a medication.

Allergic Reactions. Allergic reactions are unpredictable responses to a medication. Some patients become immunologically sensitized to the initial dose of a medication. After repeated administration of the medication, the patient develops an allergic response to the medication, its chemical preservatives, or a metabolite. The medication or chemical acts as an antigen, triggering the release of the body's antibodies. A patient's **medication allergy** symptoms may vary, depending on the individual and the medication (Table 33-2). Among the different classes of medications, antibiotics cause a high incidence of allergic reactions.

Anaphylactic reactions are severe reactions that are life-threatening and are characterized by sudden constriction of

► TABLE 33-2 Mild Allergic Reactions

Symptom	Description
Urticaria	Raised, irregularly shaped skin eruptions with varying sizes and shapes; eruptions have reddened margins and pale centre.
Rash	Small, raised vesicles that are usually reddened; often distributed over entire body.
Pruritus	Itching of skin; accompanies most rashes.
Rhinitis	Inflammation of mucous membranes lining nose; causes swelling and clear, watery discharge.

Figure 33-2 A MedicAlert bracelet is engraved with a person's emergency medical information, including drug allergies.

bronchial muscles, edema of the pharynx and larynx, severe wheezing, shortness of breath, and circulatory collapse. Immediate use of antihistamines, epinephrine, or bronchodilators is required to treat anaphylactic reactions. Emergency resuscitation measures are sometimes required. A patient with a known history of an allergy to a medication needs to avoid exposure to that medication and must wear a bracelet or medal engraved with emergency medical information, including medication allergies (e.g., a MedicAlert bracelet, Figure 33-2). These bracelets and medals alert health care workers to the patient's medical information, including allergies, if the patient is unable to communicate this information when receiving medical care. Additionally, some patients with allergies leading to anaphylactic reactions carry their own epinephrine pens.

Medication Interactions

When one medication modifies the action of another medication, a **medication interaction** occurs. Medication interactions are common in patients who take several medications. Some medications increase or diminish the action of other medications or may alter the way another medication is absorbed, metabolized, or eliminated from the body. When two medications have a **synergistic effect**, the combined effect of the two medications is greater than the effect of the medications when given separately. For example, alcohol acts as a depressant on the central nervous system and has a synergistic effect on antihistamines, antidepressants, barbiturates, and narcotic analgesics.

Sometimes a medication interaction is desired. Prescribers combine medications to create an interaction that will have a beneficial effect on the patient's condition. For example, a patient with high blood pressure may be prescribed several medications, such as diuretics and vasodilators, which act together to control blood pressure when one medication alone is not effective.

Medication Dose Responses

After administration, a medication undergoes absorption, distribution, metabolism, and excretion. Except when administered intravenously, medications take time to enter the bloodstream. The quantity and distribution of a medication in different body compartments change constantly. When a medication is prescribed, the goal is to achieve a constant blood level of the medication within a safe therapeutic range. Repeated doses are required to achieve a constant therapeutic **concentration** of a medication because a portion of a drug is always being excreted. The highest serum concentration (**peak concentration**) of a medication usually occurs just before the body absorbs the last of the medication (McKenry et al., 2006). After peaking, the serum medication concentration falls

Figure 33-3 Curve showing therapeutic blood levels of medication.
Source: From Clark, J. F., Queener, S. F., & Karb, V. B. (1998). *Pharmacological basis of nursing practice* (6th ed.). St Louis, MO: Mosby.

progressively. After intravenous (IV) infusions, the peak concentration occurs quickly, but the serum level also begins to fall immediately (Figure 33-3). The point at which the lowest amount of drug is detected in the serum is called the **trough concentration**. Some medications doses (e.g., vancomycin) are based on peak and trough serum levels. The trough level is generally drawn 30 minutes before the drug is administered, and the peak level is drawn whenever the drug is expected to reach its peak concentration. The time a drug takes to reach its peak concentration varies depending on the medication's pharmacokinetics.

All medications have a **serum half-life**, which is the time it takes for the excretion processes to lower the serum medication concentration by half. To maintain a therapeutic plateau, the patient needs to receive regular fixed doses. For example, current evidence indicates that pain medications are most effective when they are given "around the clock" to maintain an almost constant level of pain medication rather than being given when the patient intermittently complains of pain. After an initial medication dose, the patient receives each successive dose when the previous dose reaches its half-life.

Together with the patient, you need to follow regular dosage schedules and adhere to prescribed doses and dosage intervals (Table 33-3). Some agencies set schedules for medication administration. However, nurses are able to alter this schedule on the basis of knowledge about a medication. For example, at some agencies, medications prescribed to be taken once a day are given at 9:00 a.m. However, if a medication works best when given before bedtime, administer the medication before the patient goes to sleep.

When teaching patients about dosage schedules, use language that is familiar to the patient. For example, when teaching a patient about medication dosing twice a day, instruct the patient to take a medication in the morning and again in the

TABLE 33-4

Terms Associated With Medication Actions

Term	Meaning
Onset	The time it takes for a medication to produce a response after it has been administered.
Peak	The time it takes for a medication to reach its highest effective concentration.
Trough	Minimum blood serum concentration of medication, typically reached just before the next scheduled dose.
Duration	The time during which a medication is present in sufficient concentration to produce a response.
Plateau	Blood serum concentration of a medication has been reached and is maintained after repeated fixed doses.

evening. Use knowledge about the time intervals of medications to anticipate a medication's effect and to educate the patient about when to expect a response. Table 33-4 lists common terms associated with medication actions.

Routes of Administration

The route prescribed for administering a medication depends on the medication's properties, the medication's desired effect, and the patient's physical and mental condition (Table 33-5). Collaborate with the prescriber to determine the best route for a patient's medication, as in the following hypothetical situation:

Mr. Huels's temperature is 39.2° C. He complains of nausea and is unable to tolerate oral fluids. You check Mr. Huels's orders, which read, "Acetaminophen 650 mg orally for temperature above 38.5° C." Based on your assessment of Mr. Huels's nausea, you determine that

Figure 33-4 Sublingual administration of a tablet.

Figure 33-5 Buccal administration of a tablet.

he will not be able to tolerate acetaminophen orally. You consult the prescriber and receive an order for acetaminophen per rectum. By using a rectal suppository, you are able to administer the acetaminophen without increasing the patient's symptoms of nausea.

Oral Routes. The oral route is the easiest and the most commonly used route of administering medication. Medications are given by mouth and swallowed with fluid. Oral medications have a slower onset of action and a more prolonged effect than parenteral medications. In general, patients prefer taking medication orally.

Sublingual Administration. Some medications are designed to be readily absorbed after being placed under the tongue to dissolve (Figure 33-4). A medication given by the **sublingual** route should not be swallowed because the medication will not have the desired effect. Nitroglycerine is commonly given sublingually. After giving a sublingual medication, avoid giving liquids; instruct the patient not to drink anything until the medication is completely dissolved.

Buccal Administration. Administration of a medication by the **buccal** route involves placing solid medication in the mouth and against the mucous membranes of the cheek until the medication dissolves (Figure 33-5). To avoid mucosal irritation, teach patients to alternate cheeks with each subsequent dose. Advise patients not to chew or swallow the medication or to take any liquids with it. A buccal medication acts locally on the mucosa or systemically when it is dissolved in a person's saliva.

► **TABLE 33-5** Factors Indicating Choice of Administration Routes**Advantages****Oral, Buccal, and Sublingual Routes**

Convenient and comfortable for patient

Economical

Easy to administer

Medications may produce local or systemic effects.

Rarely cause anxiety for patient

Disadvantages or Contraindications

Avoid when patient has alterations in gastrointestinal function (e.g., nausea, vomiting), reduced motility (after general anaesthesia or bowel inflammation), or surgical resection of a portion of the gastrointestinal tract. Gastric secretions destroy some medications. Oral administration is contraindicated in patients who are unable to swallow (e.g., patients with neuromuscular disorders, esophageal strictures, mouth lesions). Oral medications may irritate the lining of the gastrointestinal tract, discolour teeth, or leave an unpleasant taste. An unconscious or confused patient may be unable or unwilling to swallow or hold medication under the tongue. Oral medications cannot be given when the patient has gastric suction. Oral medications are contraindicated in patients before some medical tests and surgeries.

Subcutaneous, Intramuscular (IM), Intravenous (IV), and Intradermal (ID) Routes

An alternative means of administration when oral medications are contraindicated

More rapid absorption than with topical or oral routes
IV infusion provides medication delivery when patient is critically ill or when long-term therapy is required.
If peripheral perfusion is poor, IV route is preferred over injections.

Risk of introducing infection. Some medications are expensive. Some patients experience pain from repeated needle sticks. Subcutaneous, IM, and ID routes are avoided in patients who have bleeding tendencies. Risk of tissue damage with subcutaneous injections. IM and IV routes have higher absorption rates, which places the patient at higher risk for reactions. Anxiety is caused in many patients, especially children.

Dermal Route**Topical Medications**

Primarily provide local effects
Painless
Limited side effects

Transdermal Medications

Prolonged systemic effects with limited side effects

Mucous Membranes*

Therapeutic effects are provided by local application to the affected sites.

Aqueous solutions are readily absorbed and capable of causing systemic effects.

An alternative means of administration when oral medications are contraindicated

Patients with skin abrasions are at risk for rapid medication absorption and systemic effects.
Medications slowly absorb through the skin.

Leaves oily or pasty substance on skin and may soil clothing.

Mucous membranes are highly sensitive to some medication concentrations.

Insertion of rectal and vaginal medication often causes embarrassment.

Patients with ruptured eardrums cannot receive irrigations. Rectal suppositories are contraindicated if patient has had rectal surgery or if active rectal bleeding is present.

Inhalation Routes

Provides rapid relief for local respiratory problems
Used for introduction of general anaesthetic gases

Some local inhalants can cause serious health effects.

*Includes mouth (buccal, sublingual), eyes, ears, nose, vagina, rectum, and ostomy.

Parenteral Routes. Parenteral administration involves injecting a medication into body tissues. The following are the four major sites of **injection** (which is the insertion of liquid into the body with a syringe):

Intradermal (ID): Injection into the dermis just under the epidermis

Subcutaneous: Injection into tissues just below the dermis

Intramuscular (IM): Injection into a muscle

Intravenous (IV): Injection into a vein

Some medications are administered into body cavities other than the four sites listed above. These routes of medication administration include epidural, intrathecal, intraosseous,

intraperitoneal, intrapleural, and intra-arterial routes. Depending on agency policy, additional education or certification may be required for you to administer medications through some routes. Whether you actually administer the medication by these routes, you remain responsible for monitoring the integrity of medication delivery systems, understanding the therapeutic value of the medication, and evaluating the patient's response to the therapy.

Epidural Route. Epidural medications are administered in the epidural space via a catheter, which is put in place by an anaesthesiologist. This route is often used for the administration of analgesia both intraoperatively and postoperatively

(see Chapter 41). If you have received extra education in the epidural route, you will be able to administer medications in bolus form or by continuous infusion. Be aware of agency policies regarding a patient's physical assessment following epidural medication administration.

Intrathecal Route. Intrathecal medications are administered through a catheter that has been placed into the subarachnoid space or into one of the ventricles of the brain. Intrathecal administration is often associated with long-term medication administration through surgically implanted catheters.

Intraosseous Route. This method of medication administration involves the infusion of medication directly into the bone marrow. Intraosseous routes are most commonly used in infants and toddlers because their intravascular space is difficult to access. This method is most often used when an emergency arises and IV access is impossible. The physician inserts an intraosseous infusion needle into the bone, usually the tibia, for the administration of medication by the nurse.

Intraperitoneal Route. Medications are administered into the peritoneal cavity, where they are absorbed into the circulation system. Intraperitoneal routes are used to administer chemotherapeutic agents, insulin, and antibiotics.

Intrapleural Route. An injection or a chest tube is used to administer intrapleural medications directly into the pleural space. Chemotherapeutic agents are the most common medications administered by this method.

Intra-arterial Route. Intra-arterial medications are administered directly into the arteries and are commonly used to deliver tissue plasminogen activators in patients who have arterial clots. Often, intra-arterial medications are delivered through in-dwelling catheters. You are responsible for monitoring the integrity of infusions systems and evaluating patients for adverse responses to these medications, including systemic and gastrointestinal bleeding. Ensure that you are familiar with agency protocols, policies, and procedures for patient assessment.

Other methods of medication administration that are usually limited to administration by a physician are **intracardiac** routes, in which medication is injected directly into cardiac tissue, and **intra-articular** routes, in which medication is injected into a joint.

Topical Administration. Medications applied to the skin and to mucous membranes usually result in local effects. Administer topical medications by painting or spreading the medication over the skin, applying moist dressings, soaking body parts in a solution, or giving medicated baths. Systemic effects often occur if a patient's skin is thin or broken down, if the medication concentration is high, or if the medication's contact with the skin is prolonged.

A **transdermal disc** or patch (i.e., an adhesive-backed patch that releases nitroglycerine, scopolamine, or estrogens) has systemic effects. The disc secures the medicated ointment to the skin. These topical applications may be applied for as few as 12 hours or as long as 7 days.

Medications can be applied to mucous membranes in a variety of ways: (1) by directly applying a liquid or ointment (e.g., using eye drops, gargling, swabbing the throat); (2) by inserting a medication into a body cavity (e.g., placing a suppository in the rectum or vagina or inserting medicated packing into the vagina); (3) by instilling fluid into a body cavity (e.g., use of ear drops, nose drops, or bladder and rectal instillation, and fluid is retained); (4) by irrigating a body

Figure 33-6 Medication being instilled through an endotracheal tube.

cavity (e.g., flushing with medicated fluid the eye, ear, vagina, bladder, or rectum, and fluid is not retained); and (5) by spraying (e.g., instillation into the nose or throat).

Inhalation Route. The deeper passages of the respiratory tract provide a large surface area for medication absorption. Medications can be administered through the nasal passages, the oral passage, or endotracheal or tracheostomy tubes. Endotracheal tubes are inserted into the patient's mouth and extend to the trachea (Figure 33-6), whereas tracheostomy tubes directly enter the trachea through an incision in the patient's neck. Medications that are administered by the **inhalation** route are readily absorbed and work rapidly because of the rich vascular alveolar-capillary network present in the pulmonary tissue. Inhaled medications may have either local or systemic effects.

Intraocular Route. In **intraocular** medication delivery, a medication in a form similar to a contact lens is inserted directly into the patient's eye. The eye medication disc has two soft outer layers that enclose the medication. The disc can remain in the patient's eye for up to one week. Pilocarpine, a medication used to treat glaucoma, is the most common medication delivered through the intraocular route.

Systems of Medication Measurement

The proper administration of a medication depends on your ability to compute medication doses accurately and to measure medications correctly. Mistakes can lead to a fatal error. You are responsible for checking the accuracy of the dose before you give a medication. The metric, apothecary, and household systems of measurement are used in medication therapy. Most nations, including Canada, use the metric system as their standard of measurement. Household measurements are used by health care providers when they write prescriptions to be self-administered by patients.

Metric System. Because it is a decimal system, the **metric system** (Système Internationale d'Unités [SI]) is the most logically organized system of measurement. Metric units can easily be converted and computed through simple arithmetic, such as multiplication and division. Each basic unit of measurement is organized into units of 10. Secondary units are formed by multiplying or dividing by 10. In multiplication, the

decimal point moves to the right; in division, the decimal moves to the left. For example:

$$10 \text{ mg} \times 10 = 100 \text{ mg}$$

$$10 \text{ mg} / 10 = 1 \text{ mg}$$

When designating a metric dosage, *do not write a zero alone after a decimal point* (e.g., write 5 mg, not 5.0 mg) and always include a zero before the decimal point (e.g., 0.1 mg) to comply with current guidelines (Institute for Safe Medication Practices, 2006a; Joint Commission, 2007). The basic units of measurement in the metric system are the metre (length), the litre (volume), and the gram (weight). For medication calculations, use only the measurements for volume and weight. In the metric system, the basic units are designated by the use of lowercase or uppercase letters:

Gram = g or Gm

Litre = L or l

Lower-case letters are used for abbreviations for other units:

Milligram = mg

Millilitre = mL

A system of Latin prefixes designates a subdivision of the basic units: *deci-* (1/10 or 0.1), *centi-* (1/100 or 0.01), and *milli-* (1/1000 or 0.001). Greek prefixes designate multiples of the basic units: *deka-* (10), *hecto-* (100), and *kilo-* (1000). When medication doses are written in metric units, prescribers and nurses use either divisions or multiples of a unit. Convert any fractions to the decimal form.

500 mg or 0.5 g, *not* 1/2 g

10 mL or 0.01L, *not* 1/100 L

Solutions. Solutions of various concentrations are used for injections, irrigations, and infusions. A **solution** is a given mass of solid substance dissolved in a known volume of fluid or a given volume of liquid dissolved in a known volume of another fluid. When a solid is dissolved in a fluid, the concentration is expressed in units of mass per units of volume (e.g., g/mL, g/L, mg/mL). A concentration of a solution may also be expressed as a percentage. A 10% solution, for example, is 10 g of solid dissolved in 100 mL of solution. A proportion also expresses concentrations. A 1/1000 solution represents a solution containing 1 g of solid in 1000 mL of liquid or 1 mL of liquid mixed with 1000 mL of another liquid.

Household Measurements. Household measures include drops, teaspoons, tablespoons, cups, pints, and quarts (or litres) for volume, and ounces and pounds (or grams and kilograms) for weight. Although ounces and pounds are considered household measures, they are also used in the apothecary system. The advantage of household measurements is their convenience and familiarity. When the accuracy of a medication dose is not critical, household measures can be safely used. For example, many over-the-counter medications can safely be measured by this method. To calculate medications accurately, you need to be familiar with the common

► TABLE 33-6 Equivalents of Measurement

Metric Measurement	Household Measurement
1 mL	15 drops (gtt)
4–5 mL	1 teaspoon (tsp)
15 mL	1 tablespoon (tbsp)
30 mL	2 tablespoons (tbsp)
250 mL	1 cup (c)
480 mL (approximately 500 mL)	1 pint (pt)
960 mL (approximately 1 L)	1 quart (qt)
3840 mL (approximately 5 L)	1 gallon (gal)

equivalents of metric and household units (Table 33-6). The disadvantage of household measures is their inaccuracy. Household utensils, such as teaspoons and cups, often vary in size. The scales used to measure pints or quarts are often not well calibrated.

Nursing Knowledge Base

The Institute of Medicine (IOM) (2003) published the book *To Err Is Human: Building a Safer Health System*. According to this book, in any given year, an estimated 98,000 people die from medical errors that occur in hospitals; more people die from medical errors than from motor vehicle accidents, breast cancer, and workplace injuries; and medication-related errors for hospitalized patients cost approximately \$2 billion annually.

Nurses play an important role in patient safety, especially in the area of medication administration. To safely administer medications, ensure that you know how to calculate medication doses accurately, strictly adhere to agency policy and procedure, and report any medication errors that occur. Be aware of the different roles that members of the health care team play in prescribing and administering medications. Remember to apply your previous learning to medication administration. The nursing process provides the framework for organizing your thoughts and actions, and it is the foundation for medication administration (Box 33-2).

Clinical Calculations

To administer medications safely, you need an understanding of basic arithmetic to calculate medication doses, mix solutions, and perform a variety of other activities. This skill is important because medications are not always dispensed in the unit of measure in which they are ordered (Box 33-3). This discrepancy occurs because medication companies package and bottle certain standard dosages. For example, the prescriber may order 20 mg of a medication that is available only in 40 mg vials. You frequently need to convert available units of volume and weight to the prescribed doses. Therefore, be aware of approximate equivalents in all major measurement systems.

Conversions Within One System. To convert units of measurement in the metric system, divide or multiply. To change milligrams to grams, divide by 1000, moving the decimal three places to the left.

$$1000 \text{ mg} = 1 \text{ g}$$

$$350 \text{ mg} = 0.35 \text{ g}$$

* BOX 33-2

EVIDENCE-INFORMED
PRACTICE GUIDELINEReducing Distractions During
Medication Administration

Evidence Summary

Many medication errors occur when nurses become distracted or lose focus during medication administration. Errors also occur when nurses fail to follow standard nursing protocols and procedures related to medication administration. Nurses experience multiple interruptions and distractions in today's health care environment. Systems need to be put in place to help nurses avoid these distractions and subsequent medication errors. Pape et al. (2005) used techniques to help nurses focus more acutely on medication administration. Nurses used small checklist cards that listed the steps of medication administration. The cards were similar to checklists used by pilots during the takeoff and landing of airplanes. Reported medication errors decreased after three weeks. Consequently, researchers posted "Do Not Disturb" signs in medication preparation areas to help remind everyone in the hospital not to disturb nurses during the medication administration process. Following the interventions, nurses were better able to follow the hospital's medication administration procedure, and they perceived fewer distractions during medication administration.

Application to Nursing Practice

- Consistently following nursing protocols for medication administration decreases medication errors.
- Nurses who experience fewer distractions during medication administration experience fewer medication errors.
- Placing "Do Not Disturb" signs in medication preparation areas helps reduce distractions and errors.
- Nurses need to investigate strategies that will decrease distractions, enhance their ability to follow nursing protocols, and improve their focus during medication administration.

Reference: Pape, T. M., Guerra, D. M., Muzquiz, M., Bryant, J. B., Ingram, M., Schraner, B., et al. (2005). Innovative approaches to reducing nurses' distractions during medication administration. *Journal of Continuing Nursing Education*, 36, 108–116.

to a quart measurement, divide 8 by 32 to get the equivalent, which is 0.25 quart.

Dose Calculations. Many formulas can be used to calculate medication doses. Apply the following basic formula when preparing solid or liquid doses of a medication:

$$\frac{\text{Dose ordered}}{\text{Dose on hand}} \times \text{Amount on hand} = \text{Amount to administer}$$

The dose ordered is the amount of medication prescribed. The dose on hand is the dose of medication supplied by the pharmacy (e.g., milligrams, units) and is expressed on the medication label as the contents of a tablet or capsule or as the amount of medication dissolved per unit volume of liquid. The amount on hand is the basic unit or quantity of the medication that contains the dose on hand. For solid medications, the amount on hand may be one capsule; the amount of liquid on hand may be a millilitre or litre, depending on the container. For example, a liquid medication comes in the strength of 125 mg per 5 mL. Thus, 125 mg is the dose on hand, whereas 5 mL is the amount on hand. The amount to administer is the actual amount of medication you will administer. Always express the amount to administer in the same unit as the amount on hand.

The following example illustrates how to apply the formula. The prescriber orders the patient to receive morphine 2 mg IV. Thus, the dose ordered is 2 mg. The medication is available in a vial containing 10 mg per millilitre, and the amount on hand is 1 mL. The formula is applied as follows:

$$2 \text{ mg} / 10 \text{ mg} \times 1 \text{ mL} = \text{Amount in millilitres to administer}$$

To simplify the 2/10 fraction to decimal form, divide numerator and denominator by 2:

$$1/5 \times 1 \text{ mL} = 1/5 \text{ mL or } 0.2 \text{ mL to administer}$$

Syringes are calibrated only in decimals. After converting the fraction 1/5 to 0.2 mL, prepare the correct dose.

The following is an example of how the formula applies when calculating solid dose forms. The prescriber orders 0.125 mg orally (PO) of digoxin. The medication is available in tablets containing 0.25 mg of digoxin.

$$\frac{0.125 \text{ mg}}{0.250 \text{ mg}} \times 1 \text{ tablet} = \text{Number of tablets to administer}$$

The fraction 0.125/0.250 equals 1/2 or 0.5. Therefore,

$$0.5 \times 1 \text{ tablet} = 0.5 \text{ or } 1/2 \text{ tablet to be administered}$$

Many tablets are manufactured with scores, or indentations, across the centre of the tablet (Figure 33-7). A scored tablet is easy to break in half for divided doses. Do not cut unscored tablets because the potential for an incorrect dose is high.

Often, liquid medications are manufactured in volumes greater than 1 mL. In applying the formula, be careful to use the correct concentration to avoid a medication error. For example, a medication order is for "erythromycin suspension 250 mg PO." The pharmacy delivers 100 mL bottles with the label stating, "5 mL contains 125 mg of erythromycin." Thus, to obtain the correct dose of medication, the appropriate concentration is 125 mg in 5 mL.

► BOX 33-3

Common Reasons for
Measurement Conversions

- Needing to convert fluid ounces to millilitres for measurement of intake and output
- Needing to convert body weight from pounds to kilograms and vice versa
- Needing to convert volume equivalents to calculate intravenous flow rates and to prepare wound irrigation solutions, enemas, or bladder irrigations

To convert litres to millilitres, multiply by 1000 or move the decimal three places to the right.

$$1 \text{ L} = 1000 \text{ mL}$$

$$0.25 \text{ L} = 250 \text{ mL}$$

To convert units of measurement within the apothecary system or the household system, consult an equivalence table. For example, when converting fluid ounces to quarts, recall that 32 ounces is the equivalent of 1 quart. To convert 8 ounces

Figure 33-7 Scored medication tablet. **Source:** Courtesy Mosby's GenRx 1999: The complete reference for generic and brand drugs (9th ed.). (1999). St Louis, MO: Mosby-Year Book.

$$250 \text{ mg}/125 \text{ mg} \times 5 \text{ mL} \times \text{Volume to administer}$$

The fraction 250/125 equals 2. Therefore,

$$2 \times 5 \text{ mL} = 10 \text{ mL to administer}$$

Some agencies require a nurse to double-check calculations with another nurse before administering the medication, especially when the risk of administering the wrong medication dose is high (e.g., heparin or insulin). Always double-check your calculations or confer with another nurse or health care provider if an answer to your calculation seems unreasonable.

Pediatric Doses. Use caution when calculating children's medication doses. Children metabolize medications at different rates than adults. For example, premature and newborn infants are especially vulnerable to adverse effects of medications because their livers and kidneys have not matured to full functioning levels. After the newborn period, the liver metabolizes some drugs more quickly, which may require that the child receive either larger doses or more frequent doses (Hockenberry & Wilson, 2007). Medication dosages for children are also affected by difficulty in evaluating whether the medication has the desired effect and the hydration status of the child. In most cases, the prescriber will calculate the dose for a child before ordering the medication. However, you are responsible for the safe dose range for any medication administered to a child. Be aware of the formulas used to calculate pediatric doses and recheck all doses before administration. Drug package inserts or medication references often list the normal ranges for pediatric doses. Various formulas are used to determine the appropriate medication dosages for children. These formulas are often calculated on the basis of the child's age, weight, body surface area, and the medication amount. The most accurate method of calculating pediatric doses is based on a child's body surface area (Hockenberry & Wilson, 2007). Use Mosteller's formula or the standard nomogram (e.g., the West nomogram) to estimate a child's body surface area (Figure 33-8).

Use the following formula to calculate a pediatric dose. The formula is a ratio of the child's body surface area compared with the body surface area of an average adult, which is 1.7 square metres, or 1.7 m².

$$\text{Child's dose} = \frac{\text{Surface area of child}}{1.7 \text{ m}^2} \times \text{Normal adult dose}$$

For example, a prescriber orders ampicillin for a child weighing 12 kg. The normal adult dose for ampicillin is 250 mg. According to the West nomogram (see Figure 33-8), a child weighing 12 kg has a surface area of 0.54 m². Using this information, calculate the appropriate child's dose:

$$\text{Child's dose} = 0.54 \text{ m}^2 / 1.7 \text{ m}^2 \times 250 \text{ mg}$$

Alternative (Mosteller's formula):

$$\text{Surface area (m}^2\text{)} = \sqrt{\frac{\text{Height (cm)} \times \text{Weight (kg)}}{3600}}$$

Figure 33-8 West nomogram used to estimate the body surface area of children. A straight line is drawn between a child's height and weight. The point where the line crosses the surface area column is the child's estimated body surface area. **Source:** From Behrman, R. E., Kliegman, R., & Jenson, H. B. (2004). *Nelson textbook of pediatrics* (17th ed.). Philadelphia, PA: Saunders.

The m² units are cancelled out.

$$\text{Child's dose} = 0.54 / 1.7 \times 250 \text{ mg}$$

$$0.54 / 1.7 = 0.3$$

$$\text{Child's dose} = 0.3 \times 250 \text{ mg} = 75 \text{ mg}$$

An alternative method to determine medication doses for children involves basing the amount of medication to administer (usually in milligrams) on the weight of the child (usually in kilograms). For example, a prescriber orders 5 mg/kg to be given to a child weighing 14 kg. Using this information, calculate the appropriate dosage based on the following calculation:

$$\text{Child's dose} = 5 \text{ mg/kg} \times 14 \text{ kg} = 70 \text{ mg to be delivered}$$

Collectively, the prescriber and the pharmacist help to ensure the right medication is delivered to the right patient. The prescriber is a physician most often but can also be a nurse practitioner or pharmacist depending on individual provincial legislation in this area. For example, Bill 179, the *Regulated Health Professions Statute Law Amendment Act*, gives Ontario nurse practitioners and pharmacists open prescribing

privileges. Other provinces, like Alberta, also allow pharmacists to prescribe medications.

When you administer medications, you are accountable for knowing which medications are prescribed, their therapeutic and nontherapeutic effects, and any nursing implications associated with the medications. You are responsible for performing a physical assessment of the patient (e.g., monitoring and interpreting blood pressure before administering an antihypertensive medication) and, on the basis of data from the physical assessment, for determining whether a medication is safe to administer. You should also know why the patient needs the medication and be able to determine whether the patient needs supervision when taking the medication or education about the medication and its effects. Always monitor the effect of the drug after it is administered and report any reactions to the prescriber.

Prescriber's Role

The physician, nurse practitioner, or, in some provinces, the pharmacist prescribes the patient's medication by writing a medication order (**prescription**) on a form in the patient's medical record, in an order book, or on a legal prescription pad; by transmitting the information on a paper form through a facsimile (fax) machine; or by sending the information through a computer terminal. For each medication ordered, prescribers must document the patient's diagnosis, condition, or indication for use. A prescriber may also order a medication by talking directly to the nurse or by telephone. A medication or medical treatment ordered in this way is called a **verbal order**. When you receive a verbal order, read it back and receive confirmation from the prescriber to ensure accuracy (Box 33-4). Immediately enter the order into the patient's medical record and record the time and the name of the

► BOX 33-4

Recommendations Designed to Reduce Medication Errors Associated With Verbal Medication Orders and Prescriptions

Council Recommendations to Reduce Medication Errors Associated With Verbal Medication Orders and Prescriptions

Adopted February 20, 2001

Revised February 24, 2006

Preamble

Confusion over the similarity of drug names accounts for approximately 25% of all reports to the USP Medication Errors Reporting (MER) Program. To reduce confusion pertaining to verbal orders and to further support the council's mission to minimize medication errors, the following recommendations have been developed.

In these recommendations, verbal orders are prescriptions or medication orders that are communicated as oral, spoken communications between senders and receivers face to face, by telephone, or by other auditory device.

Recommendations

- Verbal communication of prescription or medication orders should be limited to urgent situations where immediate written or electronic communication is not feasible.
- Health care organizations* should establish policies and procedures that
 - Describe limitations or prohibitions on use of verbal orders
 - Provide a mechanism to ensure validity/authenticity of the prescriber
 - List the elements required for inclusion in a complete verbal order
 - Describe situations in which verbal orders may be used
 - List and define the individuals who may send and receive verbal orders
 - Provide guidelines for clear and effective communication of verbal orders
- Leaders of health care organizations should promote a culture in which it is acceptable, and strongly encouraged, for staff to question prescribers when there are any questions or disagreements about verbal orders. Questions about verbal orders should be resolved before the preparation, or dispensing, or administration of the medication.
- Verbal orders for antineoplastic agents should *not* be permitted under any circumstances. These medications are not administered in emergency or urgent situations, and they have a narrow margin of safety.
- Elements that should be included in a verbal order include
 - Name of patient
 - Age and weight of patient, when appropriate
 - Drug name
 - Dosage form (e.g., tablets, capsules, inhalants)
 - Exact strength or concentration
 - Dose, frequency, and route
 - Quantity and duration
 - Purpose or indication (unless disclosure is considered inappropriate by the prescriber)
 - Specific instructions for use
 - Name of the prescriber and, when appropriate, the telephone number
 - Name of individual transmitting the order, if different from the prescriber
- The content of verbal orders should be clearly communicated:
 - The name of the drug should be confirmed by any of the following:
 - Spelling
 - Providing both the brand and generic names of the medication
 - Providing the indication for use
 - To avoid confusion with spoken numbers, a dose such as 50 mg should be dictated as "fifty milligrams . . . five zero milligrams" to distinguish from "fifteen milligrams . . . one five milligrams."
 - To avoid confusion with drug name modifiers, such as prefixes and suffixes, additional spelling-assistance methods should be used (i.e., S as in Sam).
 - Instructions for use should be provided without abbreviations. For example, do not record "1 tab TID"; communicate the instruction as "Give one tablet three times daily."
 - Whenever possible, the receiver of the order should *write* down the complete order to enter it into a computer, then *read* it back, and receive confirmation from the individual who gave the order or test result.
- All verbal orders should be committed immediately to writing and the written record should be signed by the individual receiving the order.
- Verbal orders should be documented in the patient's medical record, reviewed, and countersigned by the prescriber as soon as possible.

*Health care organizations include community pharmacies, physicians' offices, hospitals, nursing homes, home care agencies, and so on.
Copyright © 1998–2007, National Coordinating Council for Medication Error Reporting and Prevention. All rights reserved.

prescriber who gave the order (Joint Commission, 2007). Lastly, sign the record. Most institutions require a prescriber's signature within 24 hours after the order is made. Institutional policies vary regarding the personnel who are authorized to receive verbal or telephone orders. Nursing students cannot receive these types of medication orders. Nursing students give newly ordered medications only after the order has been written and verified by a registered nurse.

Common abbreviations are used when writing orders. Abbreviations indicate dosage frequencies or times, routes of administration, and special information for administering the medication (see Table 33-3). Caution must be exercised when you use abbreviations because some shortened forms can lead to confusion and the potential for medication errors (Table 33-7). It is important to know your agency's policies on abbreviations. Do not use error-prone abbreviations when documenting medication orders or other information about medications (Institute for Safe Medication Practices, 2006a; National Coordinating Council for Medication Error

Reporting and Prevention [NCCMERP], 2007; Joint Commission, 2007).

Types of Orders

Five types of medication orders are common in acute care settings: routine, "prn," single (one-time), "STAT," and "now" orders. Medication orders are based on the frequency and the urgency of medication administration. Some conditions change the status of a patient's medication orders. For example, in some agencies, the patient's preoperative medications are automatically discontinued after surgery, and the health care provider needs to write new medication orders (see Chapter 48). The prescriber should review the medications and write new orders when a patient is transferred to another health care agency, relocated to a different service within a hospital, or discharged.

Routine Medication Orders. A routine order is carried out until the prescriber cancels it by writing a new order or until a prescribed number of days have elapsed. A routine

► **TABLE 33-7** Abbreviations, Symbols, and Dose Designations With Potential for Errors in Medication Administration

Intended Abbreviation	Meaning	Misinterpretation	Correction
U or u	Unit	Can be mistaken for the number 0 or 4, causing a 10-fold overdose or greater (e.g., "4U" can be misread as "40," or "4u" can be misread as "44"); can be mistaken for "cc," causing the dose to be administered in volume instead of in units (e.g., "4u" can be misread as "4cc")	Write out "unit"
IU	International unit	Can be mistaken for "IV" (intravenous) or "10" (ten)	Write out "international unit"
Q.D., q.d., QD, or qd	Every day	Can be mistaken for "q.i.d.," especially if the period after the letter "q" or the tail of the letter "q" is misunderstood as the letter "l"	Write out "daily"
Q.O.D., q.o.d., QOD, or qod	Every other day	Can be mistaken for "q.d." (daily) or "q.i.d." (four times daily) if the letter "o" is poorly written	Write out "every other day"
MS, MSO ₄	Morphine sulphate	Can be mistaken for magnesium sulphate	Write out the complete drug name
MgSO ₄	Magnesium sulphate	Can be mistaken for morphine sulphate	Write out the complete drug name
µg	Microgram	Can be mistaken for "mg" (milligram)	Write the abbreviation "mcgram"
hs	At bedtime, hours of sleep (hora somna)	Can be mistaken for "half-strength"	Write out "bedtime" or "half-strength"
T.I.W. or tiw	3 times a week	Can be mistaken for 3 times a day or twice in a week	Write out "three times weekly"
S.C., S.Q., SC, and SQ	Subcutaneous	SC can be mistaken for S.L. (sublingual); SQ can be mistaken for the words "5 every": the letter "q" in "sub q" can be mistaken for the word "every" (e.g., a heparin dose ordered "sub q 2 hours before surgery" can be misunderstood as being required every 2 hours before surgery)	Write the abbreviation "subcut" or the term "subcutaneously"
D/C	Discharge or discontinue	When "discharge" is intended, can be mistaken for premature "discontinuation of medications," especially when followed by a list of discharge medications	Write out "discharge" and "discontinue"
cc	Cubic centimetres	Can be mistaken for the letter "u" (units)	Use the abbreviation "mL"

PRESCRIPTION

Superscription: The client's name, address, date of birth, and provincial health number are given for identification purposes.

Name: Arlene Casey
Address: 1010 First Street
Saskatoon, SK
PHN: 320 363 XXX
DOB: 04/20/1952
Date: March 8, 2009

Rx: Means "take thou" and per the inscription.

Rx: Amoxicillin, 500 mg
1 tablet
3 times a day for 10 days
Dispense 30 tablets

Inscription: Contains the drug name, strength, and dose.

Subscription: Directions to the pharmacist about the amount to be dispensed or refills.

Rfills: 0 times at intervals of _____

Signature: Information to be written on the label, such as directions to the client.

Jane Smith, MD
Physician's Signature
Jane Smith, MD
Physician (Please Print)

Physician Signature: The physician signs the prescription. If the drug is a controlled substance, the physician includes his or her registration number.

Figure 33-9 Sample medication prescription.

order may indicate a final date or the total number of treatments or doses. Many institutions have policies for automatically discontinuing routine orders. The following are examples of routine orders: "tetracycline 500 mg PO q6h" and "Decadron 10 mg daily $\times$ 5 days."

As-Needed ("prn") Orders. According to a "prn" order, a medication is to be given only when a patient requires it. Use your skills in objective and subjective assessment and discretion when determining whether the patient needs the medication. Often, the prescriber sets minimum intervals for the time of administration, which requires the medication not be given more often than a prescribed period of time. An example is "morphine sulphate 5 mg subcutaneously q3-4 h prn for incisional pain." This order indicates that the patient needs to wait at least three hours between doses. When administering medications, document the assessment made and the time of medication administration. Make frequent evaluation of the effectiveness of the medication and record your findings in the appropriate record.

Single (One-Time) Orders. A prescriber will often order a medication to be given only once at a specified time. This order is common for preoperative medications or medications given before diagnostic examinations: for example, "Versed 25 mg IM on call to OR" and "Valium 10 mg PO at 0900."

STAT Orders. A STAT order signifies that a single dose of a medication is to be given immediately and only once. STAT orders are often written for emergencies when the patient's condition changes suddenly: for example, "Give Apresoline 10 mg IV STAT."

Now Orders. A "now" order is more specific than a one-time order; it is used only once, when a patient needs medication quickly but not immediately, as in a STAT order. When you receive a "now" order, you have up to 90 minutes to administer the medication. An example of a "now" order is "Give Vancomycin 1 g IV piggyback now."

Prescriptions. The prescriber writes prescriptions for patients who are to be administered medications outside of the hospital setting. The prescription includes more detailed

information than a regular order because the patient must understand how to take the medication and when to refill the prescription if a refill is necessary. The parts of a prescription are illustrated in Figure 33-9. You need to assess the patient's accessibility to pharmacies and other health care resources to determine whether the patient needs additional support in the community.

Pharmacist's Role

The pharmacist prepares and distributes prescribed medications. Pharmacists work with nurses, physicians, and other health care providers to evaluate the efficacy of patients' medication. The pharmacist is responsible for filling prescriptions accurately and for ensuring the prescriptions are valid. The pharmacist in a health care agency rarely needs to mix compounds or solutions, except in the case of intravenous solutions. Most medication companies deliver medications in a form that is ready for use. The pharmacist's main task is dispensing the correct medication in the proper dosage and amount and labelling the medication accurately. The pharmacist also provides information about medication side effects, toxicity, interactions, and incompatibilities.

Distribution Systems

Systems for storing and distributing medications vary. Pharmacists provide the medications, but nurses distribute the medications to patients. Institutions that provide nursing care reserve a special area for stocking and dispensing medications. Examples of medication storage areas are special medication rooms, portable locked carts, medication cabinets with computer-controlled locking devices, and individual storage units next to patients' rooms. Ensure that all medications are in locked containers in a room (e.g., a medication room) or are under constant surveillance.

Stock Supply System. In a stock system, medications are available in quantity, in large, multidose containers. The stock system is time-consuming and costly because a nurse must dispense each medication separately for each patient.

Figure 33-10 Nurse using automated medication dispensing system.

This type of medication delivery has been associated with a high rate of medication errors and is not commonly used today.

Unit-Dose System. The unit-dose system uses portable carts containing a drawer with a 24-hour supply of medications for each patient. Each drawer is labelled with the name of a patient. The unit dose is the ordered dose of medication the patient receives at one time. Each tablet or capsule is wrapped in a foil or paper container. At a designated time each day, the pharmacist or a pharmacy technician refills the drawers in the cart with a fresh supply. The cart also contains limited amounts of “prn” and stock medications. Controlled substances are not kept in the individual patient drawers; they are kept in a larger locked drawer. The unit-dose system is designed to reduce the number of medication errors and to save the steps required when dispensing medications.

Automated Dispensing Systems. Automated medication dispensing systems (AMDS) are used successfully throughout Canada (Figure 33-10). These systems use computerized controls to dispense narcotics and unit-dose medication. Each nurse accesses the system by entering a security code. All procedures connected to an AMDS are controlled electronically via a patient’s profile. The patient’s name and drug profile must be accessed before the AMDS will dispense a medication. The nurse enters the patient’s identification number into the computer and selects the desired medication, the correct dose, and the route from a display on the computer screen. The system opens the drawer containing the medication and records the transaction. Nurses may also scan bar codes to identify the patient, medication (name, dose, route), and the nurse administering the medication. This information is then automatically recorded in a computerized database.

Nurse’s Role

Administering medications to patients requires knowledge and skills that are unique to nurses. You must first determine that the medication ordered is the correct medication. Do not assume that all medications in the patient’s drawer or pill box are to be given to the patient. Collect and interpret physical assessment data to determine whether a patient should receive a medication at a given time, administer medications correctly, and monitor the effects of prescribed medications. Assess the patient’s ability to self-administer medications. An integral part of your role is educating the patient and the patient’s family about proper medication administration and monitoring. Do not delegate any part of the medication administration

process to unregulated care providers, and use the nursing process to integrate medication therapy into nursing care.

Medication Errors. A medication error is any event that could cause or lead to a patient either receiving inappropriate medication therapy or failing to receive appropriate medication therapy. Most errors made by nurses are medication errors. A medication error can cause or lead to inappropriate medication use or patient harm. A medication error can occur when you neglect routine procedures, such as checking dose calculations; administer unfamiliar medications; neglect to administer an ordered medication; fail to comply with the ten rights of medication administration (see the section on Standards for a list of these 10 rights, p. 681); and fail to perform necessary assessments before medication administration (e.g., monitoring the patient’s blood glucose levels or blood pressure). Additional system issues that can lead to medication errors include distraction, illegible orders, transcription errors, and inappropriate use of abbreviations. Hospital medication delivery systems should be designed so that a system of checks and balances helps reduce medication errors. The most common types of medication administration errors made by students include (a) omission (i.e., a patient does not receive a prescribed medication), (b) a patient is given the improper dose or quantity, (c) the patient is given the medication at the wrong time, (d) the patient is given an extra dose, or (e) the medication is given to the wrong patient (Wolf et al., 2006).

To demonstrate accountability and acting responsibly in professional practice, you need to acknowledge your errors when they occur. Because nurses play an essential role in the preparation and administration of medications, you need to be vigilant in preventing medication errors (Box 33-5) and advocate for work environments that are conducive to safe medication administration (Box 33-6).

Medication errors can also result from the design of health care products or from procedures and systems, such as product labelling and distribution. When an error occurs, the patient’s safety and well-being is top priority. Assess the patient’s condition and notify the physician or prescriber of the medication error as soon as possible. You may need to take measures to counteract the error. After the patient’s condition has stabilized, report the incident to the appropriate person in the institution (e.g., a manager or supervisor).

When a medication error occurs, you are responsible for preparing a written occurrence or incident report, which usually needs to be filed within 24 hours of the error. The report includes the patient identification information; the location and time of the incident; an accurate, factual description of the error that occurred and measures taken to address the error; and your signature. The occurrence report is not a permanent part of the patient’s medical record and is not referred to in the record (see Chapters 8 and 17), which legally protects the health care provider and the institution. Institutions use occurrence reports to track incident patterns and to address quality improvement and risk-management issues. Many institutions have procedures in place for disclosing incidents to patients or their family members.

Report all medication errors, including errors that do not cause obvious or immediate harm and near misses. It is important for you to feel comfortable in reporting an error and not fear repercussions from managerial staff. Even when a patient suffers no harm from a medication error, the institution can still learn why the mistake occurred and what steps can be

► BOX 33-5

Steps to Take to Prevent Medication Errors

- Follow the 10 rights of medication administration.
- Be sure to read labels at least three times (comparing medication administration record with label) before, during, and after administering the medication.
- Use at least two patient identifiers whenever administering a medication.
- Do not allow any other activity to interrupt administration of medication to a patient.
- Double-check all calculations, and verify with another nurse.
- Do not interpret illegible handwriting; clarify with prescriber.
- Question unusually large or small doses.
- Document all medications as soon as they are given.
- When you have made an error, reflect on what went wrong and ask how you could have prevented the error.
- Evaluate the context or situation in which a medication error occurred. This helps to determine whether you have the necessary resources for safe medication administration.
- When repeated medication errors occur within a work area, identify and analyze the factors that may have caused the errors and take corrective actions.
- Attend in-service programs that focus on the medications commonly administered.

Adapted from National Coordinating Council for Medication Error Reporting and Prevention. (2007). *Recommendations for health care professionals to reduce medication errors associated with the label, labeling and packaging of pharmaceutical (drug) products and related devices*. Retrieved from <http://www.nccmerp.org/council/council1998-03-30b.html>. Reprinted with permission of the National Coordinating Council for Medication Error Reporting and Prevention. © 2006. Revised February 2007. All rights reserved.

taken to avoid similar errors in the future. Creating a **culture of safety** through strategies such as “Good Catch” or “Near Miss” reporting is becoming a popular method for addressing medication safety. Table 33-8 outlines error-prone conditions that lead to student nurse–related errors and specific strategies for avoiding these errors.

Medication errors often occur when a patient is transferred to a different unit within a hospital or to another health care agency. Therefore, reconciling the list of a patient’s medications during the transfer process is an important part of ensuring safe patient care (Joint Commission, 2007). Nurses play an essential role in medication reconciliation (Box 33-7).

When admitting a patient to any health care setting, compare the medications the patient took in the previous setting (e.g., at home or in another nursing unit) with the patient’s current medication orders (Ptasinski, 2007). When a patient is discharged, review the patient’s current medications with the health care providers in the new setting. This action, **medication reconciliation**, may be time-consuming, but it is an essential step in ensuring medication safety. When reconciling medications, consult with the patient, the patient’s caregivers and family members, the physician or advanced practice nurse, and the pharmacist.

Critical Thinking

Knowledge

To understand why a particular medication has been prescribed for a patient and how the medication will alter the

► BOX 33-6

Informatics and Medication Safety

Many medication errors occur when the nurse incorrectly administers medications at the patient’s bedside. The following innovations and advances in technology help to reduce the number of medication errors in nursing practice:

- Networked computers allow all the patient’s health care providers to see a current list of ordered and discontinued medications.
- Internet and intranet access allow nurses and other health care providers to access current information about medications (e.g., indications, desired effects, adverse effects) and specific agency policies that address medication administration (e.g., how fast to administer an intravenous [IV] push medication, how to administer medications through a nasogastric tube).
- In some agencies, prescribers enter medication orders directly into a networked computer system or a personal hand-held computer.
- Automated medication dispensing systems and electronic medication administration records help with medication reconciliation, administration, and documentation (Manno, 2006; Paoletti et al., 2007).
- Bar-coding technology requires nurses to scan the medication, the patient’s identification bracelet, and the nurse’s identification badge before administering the medication. This process helps to ensure compliance with the 10 rights of medication administration (Mills et al., 2006; Paoletti et al., 2007; Skibinski et al., 2007).

Application to Nursing Practice

- Actively participate in the selection and evaluation of advanced technologies and the creation of nursing policies and protocols used for medication administration.
- Always follow agency policies when administering medications.
- Implement agency policies for when the technology cannot be used (e.g., during computer down time or power outages).
- Follow the manufacturer’s guidelines for care of electronic equipment and report problems with technology immediately.

patient’s physiology and have a therapeutic effect, use knowledge you have acquired from many disciplines. For example, from physiology, you learn that potassium is a major intracellular ion. When patients do not have enough potassium in their body (hypokalemia), they experience signs and symptoms such as muscle fatigue or weakness. In some cases, severe hypokalemia is fatal because of the dysrhythmias that may occur as a result. To restore the patient’s potassium level to normal, medications may be prescribed, which will also relieve the patient’s signs and symptoms of hypokalemia.

Nurses administer a wide variety of medications, and new medications are constantly being approved for dispensation. As a result, you may not always have knowledge about the medications you are asked to administer. Responsible nurses admit what they do not know and acquire the knowledge needed to safely administer unfamiliar medications by consulting a medication book, electronic computer manuals, the prescriber, or a pharmacist.

Experience

Nursing students often have limited experience with medication administration as it applies to professional practice. Clinical experiences provide nursing students with the opportunity

► **TABLE 33-8** Error-Prone Conditions Leading to Student Nurse-Related Errors

Condition	Description	Strategies to Prevent Error
Preparing drugs for multiple patients	Preparing medications for multiple patients increases the risk of administering medications to the wrong patient.	Organize the medication process by preparing medications for one patient at a time. When preparing medications for multiple patients, apply patient labels to medication cups, removable needle caps of syringes, and IV bags. Use two unique identifiers to verify the correct patient before administering medications.
Nonstandard times	Medications scheduled for administration during nonstandard or less commonly used times are prone to dose omissions.	Develop a proactive plan with staff nurses to clarify the responsibility for administration of each ordered medication and how new medication orders received during the shift will be handled.
Documentation	When both staff nurses and student nurses are assigned to the same patients, neglecting to document or review previously administered medications can lead to dose omissions or extra doses.	Instructors and staff nurses should monitor the patient's MARs and review potential omissions with the student nurses. Both student nurses and staff nurses should use the same MAR. The patient's MAR should be taken to the patient's bedside and the drug administration should be documented immediately after the patient has been administered the medications. Review all sources of documented drug administration, especially for patients who are transferred from a different unit.
MARs unavailable or not referenced	Neglecting to take the MAR to the patient's bedside when administering medications can lead to errors.	Be involved in all verbal reports about the patients you are caring for. Always use MARs when preparing and administering medications; worksheets should not be used. Prepare medications in accordance only with the original MAR, and take the MAR to the patient's bedside for verification before administering medications. Always use two unique identifiers to verify the correct patients before administering medications.
Partial drug administration	Depending on the year of study, student nurses may not be involved in administering all of the prescribed medications to patients, such as IV medications.	For each unit that hosts student nurses, nursing instructors should provide a daily report that indicates the types of medications that the student nurses will and will not be administering.
Held or discontinued medications	Drugs that have been placed on hold or have been discontinued may be mistakenly administered when student nurses are unfamiliar with an agency's processes for holding and discontinuing medications.	At the beginning of your shift, confirm with the staff nurse responsible for your patient assignment the types of medications you will and will not be administering. Report medications that are not given when due. Agencies should annually review their procedures for holding medications and make necessary revisions to ensure that the process is clear and reliable.
Monitoring issues	Errors occur when nurses are unaware of medications that require vital signs monitoring or lab values assessment before medication administration.	Consult with nursing instructors and staff nurses regarding processes for holding or discontinuing medications. Ensure you know how to access the most recent lab values. Ensure you know which medications require vital signs monitoring (e.g., antihypertensive medications) and lab values assessment (e.g., warfarin) before being administered.
Nonspecific doses dispensed	Excessive doses have been administered when student nurses expect the drug is provided in a patient-specific dose, but the pharmacy has dispensed the drug in a larger dose or quantity.	The pharmacy should dispense medications in ready-to-use, patient-specific doses whenever possible; otherwise, provide further instructions on the MAR and the dose itself. On MARs, list the patient-specific dose first, as in the following example: "Lopressor 25 mg," followed by "25 mg = 1/2 of a 50 mg tab."
Oral liquids in parenteral syringes	Preparation of oral or enteral solutions in parenteral syringes can lead to nursing students incorrectly administering these products by the IV route.	Pharmacists should dispense all oral liquid products in oral syringes. Medication areas should be stocked with oral syringes. Use only oral syringes to prepare oral medications.

MAR, Medical administration record.

Process for Medication Reconciliation

1. Verify: Obtain a current list of the patient's medications.
2. Clarify: Ensure the accuracy of the medications, dosages, and frequencies; clarify the content of the list with as many people as necessary (e.g., the patient, caregivers, health care providers, pharmacists).
3. Reconcile: Compare new medication orders against the current list; investigate any discrepancies by contacting the patient's health care provider.
4. Transmit: Communicate the updated and verified list to caregivers and the patient as appropriate.

Adapted from Ptasinski, C. (2007). Develop a medication reconciliation process. *Nurse Manager*, 38, 18.

to apply the nursing process to medication administration. As you gain experiences in medication administration, your psychomotor skills (the steps you take to complete the task) become more refined; however, psychomotor skills represent only a small part of medication administration. The patient's attitudes, knowledge, physical and mental status, and responses can make medication administration a complex experience.

Cognitive and Behavioural Attributes

Every step of safe medication administration requires a disciplined attitude and a comprehensive, systematic approach. To be consistent with professional, ethical, and legal nursing standards, you must always accept full responsibility for all your actions related to medication administration. When administering a medication to a patient, ensure that your nursing actions do not harm the patient in any way. Do not assume that the medication ordered for the patient is the correct medication or the correct dose. You can be held accountable for administering an ordered medication that is knowingly inappropriate for the patient. Thus, for all medications that you administer, you need to be familiar with the therapeutic effect, usual dosage, laboratory interferences, and side effects. Before administering medications, you must conduct a comprehensive physical assessment of the patient and critically analyze the assessment data. You are also responsible for ensuring that patients who will self-administer medications have been properly informed about all aspects of self-administration.

Institutional policy may limit your ability to administer medications in certain units in acute care settings. You may be limited by certain medication routes or by certain dosages. In most institutions, nursing procedure manuals list the institution's policies that define the classes of medications that nurses may and may not administer. The types and doses of medications that nurses may deliver can also vary from unit to unit within the same facility. For example, Dilantin, a powerful medication that is prescribed to treat seizures, may be administered by mouth or by IV push. In large doses, Dilantin can affect the rhythm of the heart. Therefore, when a nursing unit does not have the ability to monitor the patient's heart rate and rhythm, some institutions limit the amount of Dilantin that can be given to a patient. To ensure safe medication administration, you must adhere to evidence-informed practice guidelines and agency policy and procedure. Not all prescribers are aware of the limitations of all health care institutions and may

prescribe medications that cannot be given in a particular health care setting. You must recognize this possibility and ensure that the prescriber is informed of any limitations.

Standards

Standards are actions that ensure safe nursing practice. In Canada, the activity of medication administration by registered nurses is governed by the Canadian Nurses Association's *Code of Ethics* and professional practice standards set by provincial and territorial nursing associations. Nurses are legally and ethically responsible to acquire the knowledge needed to administer medications and to uphold the patient's rights, dignity, and uniqueness in the process. To ensure safe nursing practice, each time you administer a medication, you must be aware of the 10 rights of medication administration. All medication errors can be linked, in some way, to an inconsistency in adhering to the following 10 rights of medication administration:

1. The right medication
2. The right dose
3. The right patient
4. The right route
5. The right time and frequency
6. The right documentation
7. The right reason
8. The right to refuse
9. The right patient education
10. The right evaluation

Right Medication. A medication order is required for every medication you administer to a patient. When medications are first ordered, compare the medication administration record or computer order with the prescriber's written order. Always verify new medication information when new orders are written or when patients transfer from one nursing unit or health care facility to another (Joint Commission, 2007). When preparing medications, compare the label of the medication container with the medication form. Check the label against the medication form three times: (1) before removing the container from the drawer or shelf; (2) when the amount of medication ordered is removed from the container; and (3) before returning the container to storage. Never prepare medications from unmarked containers or from containers with illegible labels (Joint Commission, 2007). When you are using unit-dose prepackaged medications, check the label against the medication administration record when taking medications out of the medication dispensing system. After you determine that the information on the patient's medication administration record is accurate, the record is used to prepare and administer the medications. Verify all medications against the medication administration record at the patient's bedside before opening the medication packages and delivering the medications to the patient.

Administer only the medications that you prepare. If an error occurs, the nurse who administers the medication is responsible. If a patient questions the medication, do not ignore the patient's concerns. An alert patient will know whether a medication is different from one previously received. In most cases, the patient's medication order has been changed; however, the patient's questions might reveal an error. If an error does occur, withhold the medication and recheck it against the prescriber's orders.

Patients who self-administer medications should keep the medications in their original labelled containers, separate from

other medications, to avoid confusion. Many hospitals request that all medication in the hospital setting be administered by nurses, rather than allowing patients to self-administer; this process ensures that patients do not receive double doses of medication. If a patient refuses a medication, you should discard it; do not return it to the original container. Unit-dose packaged medications can be saved if they are unopened. However, because of infection control, some agencies require medication to be discarded if it has been taken into a patient's room. If a patient refuses narcotics, follow the proper hospital procedure of having another nurse witness the wastage of the medication.

Right Dose. The unit-dose system is designed to minimize errors. The chance of error increases when a medication must be prepared from a larger volume or strength than needed or when the prescriber, in ordering a medication, uses a system of measurement different from what the pharmacist supplies. When you perform a medication calculation or conversion, ensure that another nurse verifies the calculated dose.

After confirming the calculated dose, prepare the medication by using standard measurement devices. Use graduated cups, syringes, and scaled droppers to measure medications accurately. At home, patients should use measuring spoons and cups, not household spoons and cups, which vary in volume.

Only tablets that are scored by the manufacturer should be broken. When you need to break a scored tablet, ensure the break is even. You may cut a tablet in half by using a knife or a pill-cutting device. Discard tablets that do not break evenly. Some agencies allow nurses to save the unadministered portion of the scored medication tablet for subsequent doses if the remaining tablet is repackaged and labelled. Verify with agency policy before administering a tablet that has been opened, cut, and repackaged. In the home care setting, pill splitting is particularly problematic. The Institute for Safe Medication Practices (2006b) has developed suggestions to help with this process. Determine whether the patient has both the motor dexterity and visual acuity needed to split tablets. If possible, prescribers need to avoid ordering medications that require splitting.

Often a nurse prepares a tablet by crushing it so that it can be mixed in food. The crushing device should always be cleaned completely before the tablet is crushed. Remnants of previously crushed medications may increase a medication's concentration or result in the patient receiving a portion of an unprescribed medication. Crushed medications should be mixed with very small amounts of food or liquid. Do not mix crushed medications with the patient's favourite foods or liquids because a medication may alter the taste of the food or liquid, and thereby decrease the patient's desire for them. Pay particular attention to this concern when administering crushed medications to pediatric patients.

safety alert Not all medications can be crushed. Some medications, such as time-released or extended-release capsules, are coated with special material to prevent the medication from being absorbed too quickly. Before crushing a medication, refer to a medication manual or another medication reference to ensure that the medication can be safely crushed.

Right Patient. Medication errors often occur because one patient receives a medication intended for another patient. An important step in administering medications safely is to

Figure 33-11 Before administering any medications, the nurse checks the patient's identification bracelet. **Source:** From deWit, S. (2009). *Fundamental concepts and skills for nursing* (3rd ed., p. 647, Fig 33-4). Philadelphia, PA: W. B. Saunders.

ensure medications are given to the right patient. Remembering every patient's name and face is difficult. To identify a patient correctly, check the medication administration record against the patient's identification bracelet and ask the patient to state his or her name to ensure that the patient's identification bracelet has the correct information (Figure 33-11).

If an identification bracelet is missing or the text is smudged or illegible, acquire a new bracelet for the patient. When asking the patient's name, you should not merely speak the name and assume that the patient's response indicates that he or she is the right person. Instead, ask the patient to state his or her full name. To avoid making the patient feel uneasy, simply explain that the question is routine for giving a medication.

Right Route. If a prescriber's order does not designate a route of administration, or if the specified route is not the recommended route, always consult with the prescriber.

When administering injections, take precautions to ensure that the medications are given correctly. Prepare injections only from preparations designed for parenteral use. The injection of a liquid designed for oral use can produce local complications, such as a sterile abscess, or fatal systemic effects. Medication companies label parenteral medications "for injectable use only."

Right Time and Frequency. Nurses must know why a medication is ordered for certain times of the day and whether the time schedule can be altered. For example, two medications are ordered: one q8h (every 8 hours) and the other three times a day. Both medications are scheduled three times within a 24-hour period. The prescriber intends the q8h medication to be given around the clock to maintain therapeutic blood levels of the medication. In contrast, you need to give the three-times-a-day medication during the waking hours. Each institution has a recommended time schedule for medications ordered at frequent intervals. You may alter these recommended times if necessary or appropriate.

The prescriber often gives specific instructions for the timing of administration of a medication. For example, when a preoperative medication is to be given "on call," you need to administer the medication when the operating room notifies the nursing unit that the patient can be transferred for surgery.

A medication ordered *pc* (after meals) is to be given within half an hour after a meal, when the patient has a full stomach. A *STAT* medication is to be given immediately.

Give priority to medications that must act at certain times. For example, insulin should be administered at a precise interval before a meal. Antibiotics should be administered on time around the clock to maintain therapeutic blood levels. All routinely ordered medications should be given within 60 minutes of the times for which they are ordered (i.e., 30 minutes before or after the prescribed time).

Some medications require you to use your clinical judgement to determine the proper time for administration. A “*prn*” sleeping medication should be administered when the patient is prepared for bed or at another time appropriate for maximum benefit. Use your judgement when administering “*prn*” analgesics. For example, you may need to obtain a *STAT* order from the prescriber if the patient requires a medication before the “*prn*” interval has elapsed. Always document your calls to the patient’s prescriber that were made to obtain a change in the medication order.

Before a patient is discharged from the hospital setting, evaluate the patient’s need for home care, especially if the patient was admitted to the hospital as the result of a problem with medication self-administration. Patients often leave the hospital with a basic knowledge of their medications but are unable to retrieve and implement this knowledge after they return home. Before discharge, evaluate whether medications are adequate or are prescribed at therapeutic levels for the patient. At home, a patient may need to take several medications throughout the day. Help patients to plan their schedules on the basis of preferred medication intervals, the medications’ pharmacokinetics, and the patients’ own daily schedule. For patients who have difficulty remembering when to take medications, make a chart that lists the times when each medication is to be taken or prepare a special container to hold each timed dose.

Right Documentation. Nurses and other health care providers use accurate documentation to communicate with each other. Correct documentation is essential to ensure safe medication administration. Because medication errors may result from inaccurate documentation, ensure that the documentation is appropriate before giving the medications. Appropriate documentation includes the patient’s name; the name of the ordered medication written out in full (no medication name abbreviations); the time the medication was administered; and the medication’s dose, route, and frequency. Common problems with medication orders are incomplete information, inaccurate dose form or strength, illegible orders or signatures, incorrect placement of decimals leading to the wrong dosage, and nonstandard terminology (Hughes & Ortiz, 2005). If any pieces of information are missing, contact the prescriber to verify the order. The prescribing health care provider is responsible for providing accurate, complete, and understandable medication orders.

After you administer a medication, complete the medication administration record according to agency policy to verify that the medication was administered as ordered. You are also responsible for documenting any preassessment data regarding the administration of certain medications (e.g., antihypertensive medications, blood glucose-lowering agents, and medications for pain management). Inaccurate documentation of medications, such as failing to document an administered medication or documenting an incorrect dose, can lead to

errors in subsequent decisions about the patient’s care. For example, errors in documentation about insulin often result in negative patient outcomes. Consider the following situation: a patient receives insulin at breakfast, but the nurse who gave the insulin neglected to document it. The nurse goes home, and a new nurse is assigned to care for the patient. The new nurse notices that the previous nurse did not document the insulin and assumes that the ordered insulin was not given. Therefore, the new nurse gives the patient another dose of insulin. Two hours later, the patient experiences a low blood glucose level that causes the patient to experience seizures. Timely and accurate documentation would have prevented this situation.

Right Reason. Nurses are professionally responsible for obtaining the rationale for prescribed medications. If you are unaware of a new medication, you have the professional responsibility to research the medication by using the following sources: the *Compendium of Pharmaceuticals and Specialties (CPS)*, drug manuals, or electronic drug information databases. When retrieving information about a medication, be attentive to nursing implications, including routes of administration, preadministration physical assessments, expected onset of action, contraindications, and follow-up nursing assessments and evaluation for both adverse effects and desired responses. You are professionally obligated to contact the prescriber for verification in any of the following situations: a prescriber orders a drug that you identify as contraindicated on the basis of either the patient’s medical history or the patient’s current condition, the ordered dose exceeds the recommended limits, or the ordered route is contraindicated for the patient. Being vigilant in critically assessing a patient’s medication regimes is essential to maintain patient safety.

Right to Refuse. With the emerging focus on patient-centred care and the recognition that patients are not passive recipients of care, more attention has been given to ensuring that the rights of patients are also upheld during the medication administration process (MacDonald, 2010). Thus, it is important to remember that a patient has the right to refuse a medication. Patients need to be informed that they have this right, but at the same time, they also need to be fully informed about the potential consequences of their refusal. If a patient refuses medication therapy, do not become defensive. Recognize that every person of consenting age has the autonomous right to refuse a medication.

Right Patient Education. In order for patients to be fully informed about their medication and the consequences of refusing to take it, it is imperative that they receive the right education about their medications and their overall treatment plan. For some patients, education may be required for family members as well, particularly if they are involved in helping patients manage their medications at home. Education should include providing information about the drug being given such as the reason for taking it, its action, and possible side effects that the patient might experience while taking it. This information is important for patients and their family members to know to ensure patient safety (Canadian Institute for Health Information [CIHI], 1998). Patients and their family members need to be involved in the decision-making process about managing and administering medications and, to achieve this, they need the right information.

Right Evaluation. Patients also need to have the right evaluation at the appropriate times. Before a medication is given, you need to check to make sure that the medication

order is correct and that the medication is available and accessible to the patient. You need to follow up with the pharmacy or prescriber if you have any concerns or questions about the medication.

You also need to make sure that any special assessments that are required have been completed, such as taking a pulse or blood pressure or checking important laboratory results that are necessary for a particular medication. If you are working in the community, it is essential to ensure that patients and/or their family members have the necessary equipment and resources that facilitate safe and effective administration of medications. This assessment should include a thorough functional and cognitive assessment since many older adults are faced with several conditions, such as cognitive impairments and physical limitations, which may affect their ability to manage their medications properly.

Once a medication has been given, careful monitoring of the effectiveness of the medication, its side effects, and signs of adverse reactions and/or drug interactions is necessary. If the medication has not achieved its desired effect, additional follow-up is needed. Within a collaborative model of care, nurses should be working closely with pharmacists and physicians if further follow-up or assessments are necessary (MacDonald, 2010).

Risk Management: Agency Policy and Procedure.

Most institutions have nursing policy and procedure manuals to guide nursing practice. These manuals are updated annually based on current evidence-informed practice literature. Policy and procedure manuals contain vital information for medication administration, including the types of medications nurses are permitted to administer, the preparation of medications, the administration of medications, and guidelines for evaluating patient's response to medications. For example, some agencies require nurses to complete specialized training to qualify them to safely administer intravenous chemotherapeutic agents. Furthermore, the administration of certain medications (e.g., intravenous inotropic medications for regulating a patient's blood pressure) are prohibited on general medicine and surgery units and permitted only in critical care areas where the patient is continuously monitored for responses to medication therapy.

Maintaining Patients' Rights. Because of the potential risks related to medication administration, patients have the right to the following:

- To be informed of the medication's name, purpose, action, and potential undesired effects
- To refuse a medication regardless of the consequences
- To have qualified nurses or physicians assess their medication history, including allergies and use of herbal therapies (Box 33-8)
- To be properly advised of the experimental nature of medication therapy and to give written consent for its use
- To receive labelled medications safely without discomfort in accordance with the 10 rights of medication administration
- To receive appropriate supportive therapy in relation to medication therapy
- To not receive unnecessary medications
- To be informed whether medications are part of a research study

Be aware of these rights and handle all inquiries by patients and their families courteously and professionally.

BOX 33-8 Nursing Assessment Questions

- What prescription and nonprescription medications do you take, when do you take them, and how do you take them? Do you have a list of medications from your pharmacy or your health care provider?
- What are your medications for?
- What side effects have you experienced?
- Have you ever stopped taking your medications? If so, why did you stop taking them?
- How do you help yourself to remember to take your medications?
- Do you have any allergies to medications or foods? If so, describe what happens when you take the medication or eat the food.
- Describe your normal eating patterns. What foods do you eat, and at what times do you normally eat?
- How do your religious or cultural beliefs influence your beliefs about your medications?
- How do you pay for your medications? Do you have additional insurance through your employer or pension plan to help cover the costs of your medication? Do you live close to a pharmacy? How do you access prescription medications in your community?
- What questions do you have about your medications?

Nursing Process and Medication Administration

Assessment

To determine the need for and potential response to medication therapy, nurses assess many factors. To ensure safe medication administration, perform thorough physical assessments of all patients before administering medications.

History

Before administering medications, you need to obtain or review the patient's medical history. A patient's medical history provides indications or contraindications for medication therapy. A patient who has disease or illness is at risk for adverse medication effects. For example, if a patient has a gastric ulcer, compounds containing aspirin will increase the likelihood of bleeding. If a patient has a long-term health condition, such as diabetes or arthritis, the patient requires medications to treat these conditions. A patient's surgical history may also indicate the use of medications. For example, after a thyroidectomy, a patient may require hormone replacement.

History of Allergies

If the patient has a history of contact allergies or allergies to medication or food, inform the other members of the health care team. Food allergies should be carefully documented because many medications include ingredients also found in food sources. For example, a patient who is allergic to shellfish may also be sensitive to any product containing iodine, such as Betadine or dyes used in radiological testing. To ensure patient safety, when patients are admitted to a hospital, they are issued an identification band that lists the medications they are allergic to. Ensure that all allergies are noted on the nurse's admission notes, the medication records, and the physician's documentation of the patient's history.

Medication Data

Assess information about each medication that the patient takes, including length of time the medication has been taken, the current dosage, and whether the patient has experienced any adverse effects. Review the medication data, including the action, purpose, normal dosages, routes, side effects, and nursing implications for administration and monitoring. Common questions to ask include the following: Is the smallest possible dose ordered? (a question pertinent for medications ordered for older adults) Can a certain medication interact with other medications the patient is taking? Are special instructions required for administering the medication? Often, several resources must be consulted to gather the information you need. Some valuable resources are pharmacology textbooks, nursing journals, the *Compendium of Pharmaceuticals and Specialties (CPS)*, online medication manuals, medication package inserts, nursing journals, and the pharmacist. You are responsible for knowing as much as possible about each medication you administer. Many nursing students prepare or purchase cards containing medication data to use as a quick resource.

Diet History

A diet history reveals the patient's normal eating patterns and food preferences. Nurses can then plan the dosage schedule more effectively and advise patients to avoid foods that may interact with their medications. Be aware of patients' cultural preferences for food, and if these foods interact with medications, provide the patients and their families with comprehensive, respectful explanations.

Patient's Perceptual or Coordination Problems

For a patient with limited perceptual, fine motor, or coordination skills, self-administration of medication may be difficult. For example, a patient with arthritis who takes insulin to manage blood glucose levels may have difficulty manipulating a syringe. Always assess the patient's ability to prepare doses and take medications correctly. If the patient is unable to self-administer medications, determine whether a family member or friend will be available to assist the patient, or collaborate with the interdisciplinary team to refer the patient to a home care service that can assist in medication administration.

Patient's Current Condition

The physical or mental status of a patient may affect whether a medication is given or how it is administered. Carefully assess a patient before giving any medication. For example, check the patient's blood pressure before giving an antihypertensive medication. A patient who is nauseated may be unable to swallow a tablet. Assessment findings also serve as a baseline in evaluating the effects of medication therapy.

Patient's Attitude Toward Medication Use

The patient's attitude about medications may reveal the patient's level of medication dependence or drug avoidance. Patients may not express their feelings about taking a particular medication, particularly if they have become dependent on it. Observe the patient's behaviour for evidence of medication dependence or avoidance. Also be aware that the patient's cultural beliefs about Western medicine could interfere with medication compliance (Box 33-9 and see Chapter 9).

* BOX 33-9 CULTURAL ASPECTS OF CARE

Influences on Medication

Administration

Health beliefs vary by culture and often influence how patients manage and respond to drug therapy. Differences in values, beliefs, and attitudes affect a patient's compliance with drug therapy. For example, cultures attach different symbolic meanings to medications and drug therapy.

Herbal remedies and alternative therapies are common in some cultures and ethnic groups and can interfere with prescribed medications. In addition, differences between the health beliefs of health care providers and their patients can affect a patient's compliance with medical therapy.

Demographic changes in both age and race can affect the nursing practice in medication administration. In addition to the psychosocial aspect of medication therapy, pharmacological research has shown that some ethnic and racial groups experience differences in drug response, metabolism, and side effects.

Implications for Practice

- Assess a patient's cultural beliefs, attitudes, and values when administering medications and teach patients about their medications.
- Resolve conflicts between medications and cultural beliefs to achieve optimal patient outcomes.
- Ask whether the patient practises any alternative therapies or takes any herbal preparations.
- If a patient is not responding to drug therapy as expected, consider whether cultural influences affect the drug response, the rate at which it is metabolized, and side effects. Bear in mind that a change in the patient's medication is sometimes necessary.
- Always exercise awareness of your personal beliefs and distinguish between your values and the patients'.

Data from Andrews, M. M., & Boyle, J. S. (2007). *Transcultural concepts in nursing care* (5th ed.). Philadelphia, PA: Lippincott; and McKenry, L. M., Tessier, E., & Hogan, M. A. (2006). *Mosby's pharmacology in nursing* (22nd ed.). St Louis, MO: Mosby.

Patient's Knowledge and Understanding of Medication Therapy

The patient's knowledge and understanding of medication therapy influence the willingness or ability to follow a medication regimen. Compliance is unlikely unless a patient understands the medication's purpose, the importance of regular dosage schedules and proper administration methods, and the medication's possible side effects. When assessing a patient's knowledge of a medication, ask, "What is it for? How is it taken? When is it taken? What side effects have you experienced? Have you ever stopped taking doses? Is there anything else you do not understand about the medication but would like to know?" When the patient has a history of poor compliance, review resources available for the purchase of medications.

Patient's Learning Needs

Determine the need for instruction by assessing the patient's level of knowledge about a medication and the resources available to help the patient to take medications regularly. You may need to explain the action and purpose of the medication, the expected side effects, the correct administration techniques,

and steps the patient can take to remember the medication regimen. If a patient has a newly prescribed medication, your instruction will need to be more involved.

❖ Nursing Diagnosis

Assessment of the patient provides data about the patient's condition, the ability to self-administer medications, medication management (e.g., diabetic management), and medication use patterns, which can be used to determine actual or potential problems with medication therapy. Certain data are defining characteristics; when clustered together, they reveal nursing diagnoses. For example, noncompliance related to a medication regimen may be indicated when a patient admits that he or she is not taking prescribed medications correctly, or when evidence shows that a medication has not reversed symptoms as expected. The following nursing diagnoses may be observed during the administration of medications:

- *Anxiety*
- *Ineffective health maintenance*
- *Health-seeking behaviours*
- *Deficient knowledge of medications*
- *Noncompliance with prescribed medications*
- *Disturbed visual sensory perception*
- *Impaired swallowing*
- *Effective therapeutic regimen management*
- *Ineffective therapeutic regimen management*

After the patient's diagnosis has been selected, identify the related factors, which guide the selection of nursing interventions. For example, the related factors of inadequate resources and lack of knowledge require different interventions. If the patient's noncompliance is related to inadequate finances, collaborate with the patient's family members, social workers, or community agencies to ensure the patient receives the necessary medications. If the related factor is lack of knowledge, initiate referrals to ensure home care nurses follow up with the patient and that they implement an extensive teaching plan.

❖ Planning

Organize care activities to ensure the safe administration of medications. Hurrying to give patients medications can lead to errors. When preparing and administering medications, it is important to minimize distractions and interruptions (Pape et al., 2005).

Goals and Outcomes

Setting goals and related outcomes will help you to use your time wisely during medication administration. For example, establish the following goal and related outcomes for a patient with newly diagnosed type 2 diabetes:

Goal: The patient will safely administer all ordered medications before discharge.

Outcomes:

- The patient will express an understanding of the desired effects and the adverse effects of medications.
- The patient will state the signs, symptoms, and treatment of hypoglycemia.
- The patient will be able to monitor and interpret blood glucose levels to determine medication management or treatment for hypoglycemia.
- The patient will establish a daily routine that will coordinate timing of medication with mealtimes.

Setting Priorities

Prioritize care when administering medications. Use information gathered from your assessment of the patient to determine whether the administration of medications is appropriate and, if it is, which medication should be given first. For example, if a patient is in pain, provide pain medication as soon as possible. If the patient is experiencing an elevated blood pressure, antihypertensive medications should be administered before other medications. Establish priorities when providing patient education about medications. Provide the most important information about the medications first. For example, because hypoglycemia is a serious side effect of insulin, the patient must be able to identify and treat hypoglycemia before learning how to administer an insulin injection.

Collaborative Care

Nurses collaborate with a variety of health care providers when administering medications. It is also important when giving instruction to collaborate with the patient's family or friends, who can reinforce the importance of medication regimens in the patient's home setting. Interdisciplinary collaboration with the prescriber, the pharmacist, and the home care case manager helps to ensure the patient receives medications safely. Ensure that patients are able to read both medication labels and printed teaching sheets. Collaborate with community resources (e.g., the home care nurse, social workers) if patients have difficulty in understanding medication management, adhering to medication routines due to functional ability, or accessing resources because of physical or financial restrictions.

When patients are hospitalized, do not postpone their medication and discharge instructions until the day of discharge. For the patient to understand medications and self-administration guidelines, you must allow sufficient time for questions and discussion. Early planning is critical. Whether a patient attempts self-administration or a nurse assumes responsibility for administering medications, the following goals and expected outcomes must be met: (a) the patient and the patient's family understand the medication therapy; (b) the patient gains the therapeutic effect of the prescribed medications without discomfort or complications; (c) the patient experiences no complications related to the route of administration; and (d) the patient can safely self-administer the prescribed medications.

❖ Implementation

Health Promotion

When working with patients to promote and maintain their health, you need to identify factors that may improve or diminish their well-being. Beliefs about health, personal motivations, socioeconomic factors, and habits (e.g., smoking) can influence the patient's compliance with the medication regimen.

Teaching the patient and the patient's family about the benefit of a medication and the knowledge needed to take it correctly is an essential component of primary health care and can promote adherence to the medication regimen (Box 33-10). Integrating the patient's health beliefs and cultural practices into the treatment plan can assist in establishing a schedule or routine with the patient. You may make referrals to community resources if the patient cannot afford to purchase the necessary medications, or if the patient cannot arrange transportation to obtain the necessary medications. You should

* BOX 33-10

FOCUS ON PRIMARY
HEALTH CARE**Improving Drug Compliance**

When a patient is discharged from hospital or sent home from a visit to a clinic, the ongoing treatment may include regularly taking medications at home. In cases of chronic illness, the success of the treatment may depend on the patient's compliance with drug therapy. Nurses can play an important role in assisting patients to comply with their medication regimen.

The following suggestions may improve patient compliance:

- Ensure that the patient and the patient's family understand the reason for the medication, proper administration of the medication, and the possible consequences of noncompliance.
- Ensure that the patient and the patient's family and friends are able to recognize symptoms of medication side effects or toxicity, such as physiological changes and alterations in behaviour. Because the patient's family members and friends are often the first people to recognize such effects in the patient, they are an important resource for ensuring patient compliance.
- Teach proper self-administration of medications to patients for all routes. For example, demonstrate how to accurately measure a liquid medication. Show the patient how to prepare and administer an injection correctly by using aseptic technique. Assess the patient's ability to self-administer injections. If a patient cannot independently self-administer injections, family members or friends can be taught to administer the injections. Alternatively, collaborate with community and home care services to administer injections when patients are discharged to their home. Provide specially designed equipment as necessary, such as syringes with enlarged calibrated scales for easier reading or Braille-labelled medication vials.
- Help the patient to address any economic issues that might affect compliance.
- Explore with the patient any factors that will influence his or her ability to comply; for some patients, keeping a daily medication log may be helpful.
- Provide a written schedule that includes the name of the medication, the dose, and a description or picture of the medication.
- Encourage patients to take their medication in conjunction with an activity they do every day, such as brushing their teeth or having breakfast.
- Help patients to organize their pills into a box with daily dividers. If compliance is a major concern, home care nurses or family members can check the box and refill it on a weekly basis.
- Work with the patient's pharmacist to ensure the pharmacy calls to remind the patient when a refill is required.

teach all patients the basic guidelines for medication safety. These guidelines ensure the proper use and storage of medications in the home (Box 33-11).

Acute Care

Patients are often hospitalized to receive expert nursing observation and documentation of their responses to medications. When receiving a medication order, several nursing interventions are essential for safe and effective medication administration.

Receiving Medication Orders. A medication order is required for any medication to be administered by a nurse.

* BOX 33-11

PATIENT TEACHING

Safe Insulin Administration**Objective**

- The patient will correctly administer subcutaneous insulin.

**Teaching Strategies**

- Instruct the patient how to determine that insulin is not out of date.
- Instruct the patient to keep insulin in its original labelled container.
- Instruct the patient to keep insulin refrigerated if necessary.
- Assess the patient's visual acuity to ensure that the patient is able to prepare the appropriate amount of insulin.
- Demonstrate how to rotate the location of insulin injection sites.
- Help the patient to determine the amount of insulin required based on the results of home capillary glucose monitoring, as ordered by the patient's health care provider.
- Observe the patient's ability to correctly assess the results of capillary blood glucose monitoring.
- Demonstrate to the patient how to prepare a single insulin preparation.
- Demonstrate to the patient how to administer a subcutaneous insulin injection.
- Show the patient how to keep a daily log book to record insulin injections, including results of home capillary glucose monitoring, type and amount of insulin given, expiration date on insulin vial, time of insulin injection, and injection site used.

Evaluation

- Ask the patient to describe the signs and symptoms of hypoglycemia and the associated interventions.
- Ask the patient to describe the procedure used at home for determining the correct dose of insulin needed and the injection site.
- Observe the patient preparing an insulin dose on the basis of the results of capillary glucose monitoring.
- Observe the patient selecting the injection site and self-administering the insulin injection.
- Review the information recorded in the patient's log book for completeness.

Before any other interventions, ensure the medication order contains all the elements in Box 33-12. If the medication order is not complete, inform the prescriber and ensure completeness before carrying out the medication order.

Correct Transcription and Communication of Orders. Nurses or a designated unit secretary sometimes write the prescriber's complete order on the appropriate medication form, the medication administration record. The transcribed order includes the patient's name, identification number, room, bed number, allergies, and the medication name, dose, frequency, and route of administration. Each time a medication dose is prepared, refer to the medication form. When the unit-dose system is used, only one transcription is necessary, which limits the opportunity for errors. When transcribing orders, ensure that names, doses, and symbols are legible. Rewrite any smudged or illegible transcriptions.

Some institutions have prescribed order entry. The prescriber enters an order directly into the computer, which avoids the need for the transcription of orders. Computer interfaces

► BOX 33-12 Components of Medication Orders

A complete medication order includes all the following information:

- **Patient's full name:** The patient's full name distinguishes the patient from other persons with the same last name. In an acute care setting, patients may also be assigned a special identification number (e.g., a medical record number) to help differentiate patients with the same names. This number may be included on the order form.
- **Date and time the order is written:** The day, month, year, and time must be listed. Designating the time that an order is written helps to clarify when certain orders are to stop automatically. If an incident occurs involving a medication error, documentation is easier when this information is available.
- **Medication name:** The prescriber will order a medication by its generic or trade name. Correct spelling is essential to prevent confusion with medications with similar spelling.
- **Dose:** The amount or strength of the medication is included.
- **Route of administration:** The prescriber uses accepted abbreviations to indicate the medication routes. Accuracy is important because some medications can be administered by more than one route.
- **Time and frequency of administration:** Nurses need to know when to initiate medication therapy. Orders for multiple doses establish a routine schedule for medication administration.
- **Signature of prescriber:** The prescriber's signature makes the order a legal request.

transfer the order to the medication administration record, the pharmacy record, and the automated dispensing system. The computer printout may be used as the medication administration record (Figure 33-12).

Always check all transcribed orders against the original order for accuracy and thoroughness. If an order is incorrect or inappropriate, consult the prescriber. If you give the wrong medication or an incorrect dose, you are legally responsible for the error. Other health care providers involved in the error are also legally responsible.

Accurate Dose Calculation and Measurement.

When measuring liquid medications, use a standard measuring container to reduce the chance of error. Calculate each dose when preparing the medication, pay close attention to the process of calculation, and avoid interruption from other nursing activities (Pape et al., 2005).

Consult with other nurses when calculating a new or unusual dose.

Correct Administration. To help ensure safe administration, use aseptic techniques and proper procedures when handling and giving medications. Verify the patient's identity by using at least two patient identifiers (Joint Commission, 2007) and perform the necessary assessments (e.g., assessing heart rate before giving antidysrhythmic medications). Carefully monitor the patient's response to medication, especially when administering the first dose of a new medication. Document the patient's response on the appropriate record forms.

Recording Medication Administration. After administering a medication, record it immediately on the appropriate record form (see Figure 33-12). Never chart a medication before administering it. Recording the medication immediately after its administration prevents errors.

The recording of a medication includes writing the name of the medication, the dose, the route, and the exact time of administration. Record assessment parameters (e.g., blood glucose level, blood pressure, pain score) and the site of any injections, in accordance with agency policy.

If a patient refuses a medication or undergoes tests or procedures that result in a missed dose, the reason the medication was not given must be recorded in both the medication administration record and nurse's notes.

Restorative Care

Medication administration activities vary among the numerous types of restorative care settings. Patients with functional limitations may require you to fully administer all medications. In the home setting, patients usually administer their own medications. Regardless of the type of medication activity, you are responsible for instructing patients and their families in medication action, administration, and side effects. Additionally, you need to monitor the patient's compliance with medication and determine the effectiveness of medications that have been prescribed.

Special Considerations for Administering Medications to Specific Age Groups

A patient's developmental level affects the way that nurses administer medications. Your knowledge of a patient's developmental needs helps you to anticipate responses to medication therapy.

Infants and Children. Children vary in age, weight, body surface area, and their ability to absorb, metabolize, and excrete medications. Children's medication doses are lower than doses for adults; therefore, special caution is needed when preparing medications for children. Medications are usually not prepared and packaged in standardized dose ranges for children. Preparing an ordered dose from an available amount of medication requires careful calculation.

All children require special psychological preparation before receiving medications. The child's parents are valuable resources for learning the best way to administer medications to their child. Sometimes the child will experience less trauma if a parent administers the medication and you supervise.

Supportive care is needed if a child is expected to cooperate. Explain the procedure to the child, using short words and simple language appropriate to the child's level of comprehension. Long explanations may increase the child's anxiety, especially for painful procedures such as an injection. You need to administer medications to children even when they refuse to cooperate or resist consistently despite explanation and encouragement. If the child is uncooperative, administer the medication to the child quickly and carefully (Hockenberry & Wilson, 2007). If you are able to involve the child, you may have greater success giving a medication. For example, when you say, "It's time to take your tablet now. Do you want it with water or juice?" you are allowing the child to make a choice. Do not give the child the option of not taking a medication. After a medication is given, praise the child; you may even offer a simple reward such as a star or a token. Tips for administering medications to children are listed in Box 33-13.

Older Adults. Older adults also require special consideration during medication administration (Box 33-14). In addition to physiological changes of aging (Figure 33-13), behavioural and economic factors influence an older person's use of medications.

► BOX 33-13

Tips for Administering Medications to Children

Oral Medications

- Use liquid forms when available. They are safer for children to swallow and they help to avoid aspiration.
- Use droppers to administer liquids to infants.
- If older children have difficulty swallowing pills, suggest that they put the pill in their mouth and then sip liquid through a straw. The suction action pulls the liquid up the straw and makes it easier to swallow the pill.
- Offer juice, a soft drink, or a frozen juice bar after a medication is swallowed.
- To reduce nausea, pour carbonated beverages over finely crushed ice.
- When medications are mixed with palatable flavourings, such as syrup or applesauce, use only a small amount. Avoid mixing a medication with foods or liquids that the child enjoys because the child may in turn refuse them.
- A plastic, disposable syringe is the most accurate device for preparing liquid doses, especially doses of less than 10 mL (cups, spoons, and droppers are inaccurate.)
- When administering liquid medications, use a spoon, a plastic cup, or an oral syringe (without needle).

Injections

- Use caution when selecting IM injection sites for infants and small children. The deltoid muscle, which can be used for adults and older children, is underdeveloped and should not be used in infants and small children.
- Children can be unpredictable and uncooperative. Ensure that someone (preferably another nurse) is available to restrain a child if physical control is needed. The parent should act as a comforter, not a restrainer.
- Always awaken a sleeping child before giving him or her an injection.
- Distracting the child with conversation, a ringing bell, or a toy may reduce the child's perception of pain.
- Give the injection quickly and do not argue with the child.
- If time allows, use a eutectic mixture of local anaesthetics (EMLA) cream.

Polypharmacy. Polypharmacy occurs when the patient takes two or more medications to treat the same illness, when the patient takes two or more medications from the same chemical class, when the patient uses two or more medications with the same or similar actions to treat several disorders simultaneously, or when a patient mixes nutritional supplements or herbal products with medications (Brager & Soland, 2005; Ebersole et al., 2004). Older adults also often experience polypharmacy when they self-medicate to seek relief from a variety of symptoms (e.g., pain, constipation, insomnia, and indigestion) by using over-the-counter (OTC) preparations, traditional folk medicines, or herbal remedies. OTC medications contain many different ingredients; when used inappropriately, they can cause undesirable side effects and adverse reactions, or they may be contraindicated by the patient's condition.

Because many older adults suffer chronic health problems, polypharmacy is common. The patient who experiences polypharmacy is at an increased risk of adverse reactions and medication interactions with other medications and food.

* BOX 33-14 FOCUS ON OLDER ADULTS

- Simplify the drug therapy plan whenever possible (McKenry et al., 2006).
- Keep instructions clear and simple and provide written material in large print (Ebersole et al., 2004).
- Assess the patient's functional status to determine whether the patient requires assistance in taking medications (McKenry et al., 2006).
- Have the patient drink a little fluid before taking oral medications to ease swallowing. Encourage the patient to drink at least 150 to 180 mL of fluid after taking medications (Ebersole et al., 2004).
- Older adults may have a greater sensitivity to drugs, especially drugs that act on the central nervous system. Therefore, you need to carefully monitor patients' responses to medications and anticipate dosage adjustments as needed (Meiner & Luekenotte, 2006).
- If the patient has difficulty swallowing a capsule or tablet:
- Ask the physician to substitute a liquid medication if possible (Ebersole et al., 2004).
- Ask the patient to sit up straight and to tuck in the chin to decrease risk of aspiration (McKenry et al., 2006).
- Teach alternatives to medications, such as proper diet in place of vitamins and exercise in place of laxatives (Ebersole et al., 2004).
- On a frequent basis, review the patient's medication history, including over-the-counter medications (Meiner & Luekenotte, 2006).

Polypharmacy can be divided into two types: rational polypharmacy and irrational polypharmacy. Rational polypharmacy occurs when patients need to take several medications to treat their health conditions, which is often the case for older adults. For example, many older adults take multiple medications to lower their blood pressure. Irrational polypharmacy occurs when the patient takes more medications than needed. Irrational polypharmacy results from several causes. For example, some older adults need to see more than one health care provider to treat their different health conditions. When health care providers fail to take an accurate medication history or do not communicate with each other, the result can be patients taking many different medications, which increases their risk of polypharmacy (Brager & Soland, 2005).

Noncompliance. Noncompliance is defined as a deliberate misuse of medication, such as not taking a prescribed medication or altering the dose of a medication. In general, noncompliance occurs either because of drug ineffectiveness, uncomfortable side effects, or the prohibitive cost of the medicine.

◆ Evaluation

Nurses monitor patient responses to medications on an ongoing basis. For each medication, you require knowledge of the desired effect, the therapeutic action, and the common side effects. A change in a patient's condition can be physiologically related to health status, medications, or both. Be alert for reactions in a patient who takes several medications. To achieve the goal of safe and effective medication administration, a

Figure 33-13 The aging body and drug use. **Source:** From Lewis, S. M., Dirksen, S. R., Heitkemper, M. M., Bucher, L. L., & Camera, I. M. (Eds.). (2011). *Medical-surgical nursing: Assessment and management of clinical problems* (8th ed., p. 76; Fig. 5-10). St Louis, MO: Mosby.

careful evaluation of both the patient's response to therapy and the patient's ability to assume responsibility for self-care is required.

To evaluate the effectiveness of nursing interventions in meeting established goals of care, use evaluative measures to identify whether patient outcomes were met. Apply various evaluation measures in the context of medication administration, including direct observation of the patient's behaviour or response, rating scales and checklists, and oral questioning. Physiological measurement is the most common method of evaluation. Examples of physiological measures are blood pressure, heart rate, and visual acuity. Patient statements can also be used as evaluative measures. Table 33-9 gives examples of goals, expected outcomes, and corresponding evaluative measures.

Medication Administration

Medication administration is an essential part of nursing practice and requires a sound knowledge base in anatomy, physiology, pathophysiology, pharmacology, psychology, and research. The following sections illustrate the steps involved in administering medications through various routes.

Oral Administration

The easiest and most desirable way to administer medications is by mouth (Skill 33-1). Patients usually are able to ingest or self-administer oral medications with few problems. Most tablets and capsules should be administered and swallowed with approximately 60 to 100 mL of fluid (as allowed). Some situations contraindicate administering medications by mouth.

The primary contraindications to giving oral medications include the presence of gastrointestinal (GI) alterations, the inability of the patient to swallow food or fluids, and the use of gastric suction. An important precaution to take when administering any oral preparation is to protect patients from aspiration. Aspiration occurs when food, fluid, or medication intended for GI administration is inadvertently administered into the respiratory tract. Protect the patient from aspiration by assessing the patient's ability to manage oral medications. Box 33-15 describes techniques you can use to protect the patient from aspirating. Properly positioning the patient is also essential in preventing aspiration. Position the patient in a seated position when administering oral medications, if such a position is not contraindicated by the patient's condition. Having the patient slightly flex the head in a chin-down position usually reduces aspiration (Metheny, 2006). Use a

► **TABLE 33-9** Example Evaluation for Patient Goals**Goals**

The patient and the patient's family understand the patient's medication therapy.

The patient safely self-administers medications.

Expected Outcomes

The patient and the patient's family describe information about the medication, its dosage, schedule, purpose, and adverse effects.

The patient and the patient's family identify situations that require medical intervention.

The patient and the patient's family demonstrate the appropriate administration technique.

The patient follows a prescribed treatment regimen.

The patient performs administration techniques correctly.

The patient identifies available resources for obtaining the necessary medication.

Expected Outcomes

Written measurement: Ask the patient to write out the medication schedule for a 24-hour period.

Oral questioning: Ask the patient to describe the purpose, dosage, and adverse effects of each prescribed medication.

Oral questioning: Ask the patient's family to describe what to do if the patient has adverse effects from a medication.

Direct observation: Ask the patient to demonstrate the filling of an insulin syringe and self-injection.

Anecdotal notes: Have the patient's family keep a log of the patient's compliance with therapy for 1 week.

Direct observation: Observe while the patient instills eye drops.

Oral questioning: Ask the patient's family to identify how to contact the local pharmacy or community clinic to obtain the patient's medications.

► **BOX 33-15** Protecting the Patient From Aspiration

- Determine the patient's ability to swallow.
- Assess the patient's cough.
- Determine the presence of a gag reflex.
- Prepare oral medications in the form that is easiest for the patient to swallow.
- Allow the patient to self-administer medications if possible.
- If the patient has unilateral weakness, place the medication in the stronger side of the mouth.
- Administer pills one at a time, ensuring that each pill is properly swallowed before the next one is introduced.
- Thicken regular liquids or offer fruit nectars if the patient cannot tolerate thin liquids.
- Have the patient hold and drink from a cup if possible.
- When possible, medications should be timed to coincide with mealtimes or when the patient is well rested and awake.
- Administer medications through another route if risk of aspiration is severe.

multidisciplinary approach (e.g., consult with a speech therapist, a dietitian, and an occupational therapist) with patients who have difficulty swallowing (Morris, 2006).

For patients with nasogastric feeding tubes, liquid medications are preferred, but some tablets can be crushed and some capsules can be opened to mix in a solution for administration (Box 33-16).

Topical Medication Applications

Topical medications are medications that are applied locally, most often to intact skin but also to mucous membranes. They are prepared in many forms, including lotions, pastes, and ointments (see Table 33-1).

Skin Applications. Because many locally applied medications, such as lotions, pastes, and ointments, cause both systemic and local effects, apply these medications with the use of gloves and applicators. Use sterile techniques if the patient has an open wound. Skin encrustation and dead tissues harbour microorganisms and block contact of the medications from the tissues to be treated. Before applying medications, clean the area to be treated thoroughly by washing the skin gently with soap and water, soaking an involved site, or locally debriding tissue (see Chapter 46).

Apply each type of topical medication according to the directions to ensure proper penetration and absorption. When applying ointments or pastes, spread the medication evenly over the involved surface and cover the area well without applying an overly thick layer. Prescribers may order a gauze dressing to be applied over the medication to prevent soiling of clothes and wiping away of the medication. Lightly spread lotions and creams onto the skin's surface; rubbing often causes irritation. Apply a liniment by rubbing it gently but firmly into the skin. After that, dust a powder lightly to cover the affected area with a thin layer. During any application, assess the skin thoroughly. When you record the administration, note the area where the medication was applied, the name of the medication, and the condition of the skin.

Some topical medications are applied in the form of a transdermal patch that remains in place for an extended period of time (e.g., 12 hours or 7 days). Many patches are clear, which makes them difficult to see. Nurses and patients may inadvertently leave old transdermal patches in place, which results in the patient receiving an overdose of the medication. Therefore, carefully assess the patient's skin and ensure that you remove the existing patch before applying a new patch. The following guidelines are used to ensure safe administration of transdermal or topical medications (Institute for Safe Medication Practices, 2007):

Text continued on p. 697

► SKILL 33-1 Administering Oral Medications**Delegation Considerations**

The administration of oral medications cannot be delegated to unregulated care providers (UCPs). Instruct UCPs to report the occurrence of medication side effects immediately.

Equipment

- Medication cart or tray
- Disposable medication cups
- Patient identification labels
- Glass of water, juice, or preferred liquid
- Drinking straw
- Pill-crushing device (optional)
- Medication administration record or computer printout

Procedure**STEPS**

1. Check the accuracy and completeness of each medication administration record (MAR) or computer printout against the prescriber's original medication order. Check the patient's name and the medication name, dosage, route, and time for administration. Copy or rewrite any portion of the MAR that is difficult to read.
2. Assess the patient for any contraindications to receiving oral medication: Is the patient experiencing nausea or vomiting? Has the patient received a diagnosis of bowel inflammation or reduced peristalsis? Has patient undergone recent gastrointestinal (GI) surgery? Does patient have gastric suction? Is the patient restricted to nothing by mouth (NPO)? Check the patient's reflexes for swallowing, coughing, and gagging.
3. Assess the patient's medical history, history of allergies, medication history, and diet history. List the patient's food and drug allergies on each page of the MAR and prominently display the allergies on the patient's medical record. This information may also be added to an identification bracelet.
4. Gather information from the patient's physical examination and laboratory data that may influence medication administration (e.g., vital signs, blood glucose levels, electrolyte levels, laboratory findings related to blood clotting times and to renal and liver function).

RATIONALE

- The order sheet is the most reliable source and only legal record of medications the patient is to receive. Adherence to the order ensures the patient receives the correct medications. Illegible MARs are a source of medication errors.
- Alterations in GI function interfere with a medication's ability to be distributed, absorbed, and excreted. Patients with GI suction might not receive benefit from medications because they are suctioned from the GI tract before they can be absorbed. Patients with impaired swallowing are at risk for aspiration (Metheny, 2006).
- The information reflects the patient's need for medications and the potential responses to medications. Communication of the patient's potential food and drug interactions and allergies is essential for safe, effective care.
- Physical examination or laboratory data may contraindicate medication administration. Poor liver and kidney functions affect the metabolism and excretion of medications (McKenry et al., 2006).

Critical Decision Point: If the patient has any contraindications for receiving oral medications, or if you are in doubt of the patient's ability to swallow oral medications, temporarily withhold medication and inform the prescriber.

5. Assess the patient's knowledge regarding health and medication use.
 - This assessment helps to determine the patient's need for medication education and whether the patient adheres to medication therapy at home. The assessment may reveal difficulties with medication use problems, such as medication intolerance, noncompliance, abuse, addiction, or dependence.
6. Assess the patient's preferences for fluids. Maintain fluid restriction when applicable.
 - Offering fluids during medication administration increases the patient's fluid intake. Fluids ease swallowing and facilitate absorption from the GI tract. Fluid restrictions must be maintained when applicable.
7. Prepare medications:
 - A. Perform hand hygiene.
 - B. If a medication cart is used, move it to a location outside the patient's room.
 - C. Unlock the medicine drawer or cart or log on to the automated medication dispensing system.
 - D. Prepare medication for one patient at a time. If you are using paper copies of the MAR, keep all pages for one patient together. If you are using the patient's medication administration on the computer, view only one computer screen at a time.
 - Proper hygiene reduces the transfer of microorganisms.
 - Organization of equipment saves time and reduces the chance for error.
 - Medications are safeguarded when locked in cabinet or cart. Storage in a locked area prevents preparation error.
 - Preventing distractions limits preparation errors (Pape et al., 2005).

Continued

SKILL 33-1 Administering Oral Medications—cont'd

- E. Select the correct medication from a stock supply or a unit-dose drawer. Compare the label on the medication with the MAR (see Step 7E illustration) or the computer screen. Check the expiration date on all medication labels.
 - F. Calculate the medication dose as necessary. Double-check all calculations, and verify your calculations with another nurse.
 - G. If you are preparing a controlled substance, check the patient's MAR or computer record to determine the last time the medication was administered. Check the record for the previous medication count and compare the current count with the supply available.
 - H. To prepare tablets or capsules from a floor stock bottle, pour the required number into the bottle cap and transfer the medication to a medication cap. Do not touch the medication with your fingers. Return extra tablets or capsules to the bottle. Break scored medications. If necessary, use a clean pillating device. Identify scored tablets by looking for a line that divides the tablet in half.
 - I. To prepare unit-dose tablets or capsules, place the packaged tablet or capsule directly into a medicine cup. Do not remove the wrapper (see Step 7I illustration.)
- Comparing the labels on the medication with the transcribed orders reduces the chance for error. *This is the first accuracy check.*
 - Double-checking reduces the risk of error.
 - Checking the medication count reduces the risk of double-dosing if the patient is receiving controlled substances on a "prn" schedule.
 - Controlled substance laws require nurses to carefully monitor and count any dispensed narcotics.
 - A clean technique is required of medication administration. Cleaning the pillating (or pill-cutting) device ensures prior medications are cleaned out of the device and cannot contaminate this tablet. To ensure that you give the accurate dose to patient, split only those tablets that are scored.
 - Wrappers maintain the cleanliness of medications and allow the nurse to identify the medication name and dose at the patient's bedside.

Step 7E The nurse verifies each medication with the MAR.

Step 7I Place tablet into medicine cup without removing wrapper.

Critical Decision Point: If you are preparing narcotics, check the narcotic record for the previous drug count and compare it against the supply available. You are responsible for being aware of and upholding laws regarding the use of controlled substance.

- J. Place all tablets or capsules to be given to patient in one medicine cup, with the patient's identification label attached, except for those medications that require preadministration assessments (e.g., pulse rate or blood pressure); keep medications in their wrappers. After medication administration, remove the patient's identification label and discard the label in the appropriate confidential waste disposal receptacle.
- Labelling the patient's medication cup reduces the risk of administering medications to the incorrect patient.
- Keeping medications that require preadministration assessments separate from other medications makes it easier for the nurse to withhold medications as necessary.
- Disposing of the patient's label in confidential waste receptacles is necessary to protect patient confidentiality.

Critical Decision Point: Not all medications can be crushed (e.g., capsules and enteric-coated drugs). When in doubt whether a medication can be crushed, consult with your pharmacist. When pills are crushed, the patient is more likely to experience choking or aspiration of particles of medication or soft food.

► SKILL 33-1 Administering Oral Medications—cont'd

K. If the patient has difficulty swallowing, and liquid medications are not an option, use a pill-crushing device, such as a mortar and pestle to grind the pills (see Step 7K illustration). Before using a mortar and pestle, clean them. If a pill-crushing device is not available, place the tablet inside a medication cup, place another medication cup on top of it, and press on the top cup with a blunt instrument until the pill is crushed. Mix the ground tablet in small amount of soft food (custard or applesauce).

Step 7K Pill-crushing device used to crush pills when necessary.

L. To prepare liquids:

- (1) Gently shake the container. If the medication is in a unit-dose container with the correct amount to administer, no further preparation is needed. If the medication is in a multidose bottle, remove the bottle cap from the container and place the cap so that the inside of the cap is not exposed.
- (2) Hold a multidose bottle with the label against the palm of your hand while pouring.
- (3) Hold the medication cup at eye level and fill to the desired level on the scale (see Step 7L[3] illustration). The scale should be even with the fluid level at its surface or the base of the meniscus, not at its edges. Draw up volumes of less than 10 mL in a syringe without a needle (see Step 7L[3] illustration).

- Large tablets can be difficult to swallow. A ground tablet mixed with palatable soft food is usually easier to swallow. Cleaning pill-crushing devices ensures that contamination of medications does not occur.

- Shaking the container ensures the medication is mixed before administration. Correct placement of the cap of the bottle avoids contamination.
- Hold the bottle so that any spilled liquid will not soil or fade the label.
- Filling medication properly ensures accuracy of measurement. The use of a syringe enables greater accuracy for small doses of medication.

A

B

Step 7L (3) A, Pour the desired volume of liquid so that the base of the meniscus is level with the line on the scale. B, Use a needleless syringe to draw up volumes of less than 10 mL.

- (4) Discard any excess liquid into a sink. Wipe the lip and neck of the multidose bottle with a paper towel.

- These steps prevent contamination of the bottle's contents and prevent the bottle cap from sticking to the counter.
- Avoids unnecessary manipulation of the dose.

Continued

► SKILL 33-1 Administering Oral Medications—cont'd

- M. Compare the MAR, computer printout, or computer screen with the prepared medication and container.
 - N. Return stock containers or unused unit-dose medications to the storage shelf or drawer and read the labels again.
 - O. Do not leave medications unattended.
8. Administering medications:
- A. Take medications to the patient at the correct time.
 - B. Identify the patient by using at least two patient identifiers. Compare the patient's name and one other identifier (e.g., the hospital identification number) on the MAR, computer printout, or computer screen with information on the patient's identification bracelet. Ask the patient to state his or her name if possible, for a third identifier.
 - C. Compare labels of the medications with the MAR at the patient's bedside.
 - D. Explain to the patient the purpose of each medication and its action.
Encourage the patient to ask any questions about the drugs.
 - E. Assist the patient to a sitting position (or side-lying position if sitting is contraindicated).
 - F. Administer medications:
 - (1) *For tablets:* The patient may wish to hold solid medications in the hand or in a cup before placing them in the mouth.
 - (2) Offer water or juice to help the patient swallow the medications. Give cold carbonated water if it is available and not contraindicated.
 - (3) *For sublingual-administered medications:* Have the patient place the medication under the tongue and allow it to dissolve completely (see Figure 33-4). Caution the patient against swallowing the tablet.
 - (4) *For buccal medications:* Have the patient place the medication in the mouth against the mucous membranes of the cheek until it dissolves (see Figure 33-5). Avoid administering liquids until the buccal medication has dissolved.
 - (5) *For powdered medications:* Mix with liquids at bedside and give to the patient to drink.
 - (6) Caution the patient against chewing or swallowing lozenges.
 - (7) Give effervescent powders and tablets immediately after they have dissolved.
 - G. If the patient is unable to hold medications in the hand or in a cup, place the medication cup to the patient's lips and gently introduce each drug into the mouth, one at a time. Do not rush.
 - H. If a tablet or capsule falls to the floor, discard it and repeat the preparation.
 - I. Stay at the bedside until the patient has completely swallowed each medication. If you are uncertain whether the medication was swallowed, ask the patient to open the mouth.
- Reading labels a second time reduces the chance for error. *This is the second accuracy check.*
 - The *third accuracy check* of medication labels in multiple-dose containers further reduces administration errors.
 - Nurses are responsible for the safekeeping of drugs.
 - Medications are administered within 30 minutes before or after the prescribed time to ensure the intended therapeutic effect. Give STAT medications immediately or single-order medications at the time they are ordered.
 - These steps comply with the Joint Commission's (2007) requirements and improve medication safety. In most acute care settings, the patient's name and identification number on an armband and the MAR is used to identify patients. Identification bracelets are made at the time of the patient's admission and are the most reliable source of identification. The patient's room number is not an acceptable identifier.
 - Perform a final check of medication labels against the MAR at the patient's bedside to reduce medication administration errors.
 - The patient has the right to be informed; questions often indicate the need for teaching and reveal noncompliance with therapy or potential medication errors. A patient's understanding of the purpose of each medication improves compliance with medication therapy.
 - A sitting position prevents aspiration during swallowing (Metheny, 2006).
 - The patient can become familiar with medications by seeing each drug.
 - Offering a choice of fluids promotes the patient's comfort and can improve fluid intake. Carbonated water helps passage of the tablet through the esophagus.
 - Medication is absorbed through the blood vessels of the undersurface of the tongue. If medication is swallowed, it is destroyed by gastric juices or detoxified by the liver so rapidly that therapeutic blood levels are not attained.
 - Buccal medications act locally on mucosa or systemically as they are swallowed in saliva.
 - When prepared in advance, powdered medications may thicken and even harden, which makes swallowing difficult.
 - Medication acts through slow absorption through oral mucosa, not gastric mucosa.
 - Effervescence improves the unpleasant taste of the medication and often relieves GI problems.
 - Administering a single tablet or capsule eases swallowing and decreases the risk of aspiration.
 - Medication is contaminated when it touches floor.
 - You are responsible for ensuring the patient receives the ordered dose. If left unattended, the patient may not take the dose or may save medications, which could cause a risk to health.

Critical Decision Point: Replace patient identification bracelets that are missing, illegible, or faded.

► SKILL 33-1 Administering Oral Medications—cont'd

- J. For highly acidic medications (e.g., aspirin), offer the patient a nonfat snack (e.g., crackers) if it is not contraindicated by the patient's condition.
- K. Assist the patient in returning to a comfortable position.
- L. Replenish the stock, such as cups and straws. If a medication cart was used, return the cart to the medication room. Clean the work area.
- 9. Evaluate the patient's response to medications at times that correlate with the medication's onset, peak, and duration.
- 10. Ask the patient or the patient's family member to identify the medication name and explain the purpose, action, dosage schedule, and potential side effects of the drug.
- A nonfat snack reduces the possible gastric irritation from highly acidic medication.
- The patient's comfort is maintained.
- A clean and organized work space helps other staff to complete their duties efficiently.
- You can evaluate the medication's therapeutic benefit and detect the onset of side effects or allergic reactions.
- You can determine the level of knowledge gained by the patient and the patient's family.

Unexpected Outcomes

Adverse effects (e.g., side effects, toxic effects, allergic reactions)

Patient refuses medication

Related Interventions

- Symptoms such as urticaria, rash, pruritus, rhinitis, and wheezing may indicate an allergic reaction.
- Withhold further doses, and add allergy information to the patient's health record
- Always notify the prescriber and the pharmacy when the patient exhibits adverse effects.
- Explore reasons why the patient does not want the medication.
- If misunderstandings of the medication therapy are apparent, address the misconceptions by educating the patient.
- Do not force the patient to take the medication; patients have the right to refuse treatment.
- If the patient continues to refuse medication despite your attempts to educate, record on patient's chart why the drug was withheld and notify the prescriber.

Recording and Reporting

- Record the administration of oral medications on the computerized or paper copy of the medication administration record immediately after administering the medications. If you are using a paper copy of the medication administration record, include your initials or signature.
- Record the reason any drug was withheld and follow the agency's policy for proper recording.
- Record and report your evaluation of the medication's effect to the prescriber if required (e.g., report urine output following administration of a diuretic if ordered by the prescriber).

Home Care Considerations

- To ensure safe medication administration at home, instruct patients on all aspects of medication administration, including dosage, desired effect, when to take the medications, proper storage of the medications, anticipated side effects, and whether to take medication with or without food.
- Evaluate the patient's ability to safely self-administer medications. If the patient needs assistance in self-administration, introduce nursing interventions, such as a chart or pillbox. If interventions fail and the patient still is unable to safely administer medications, notify the prescriber.

1. Document on the medication administration record or computer record the area where the medication was applied.
2. When applying a transdermal patch, ask the patient whether he or she has an existing patch.
3. Do not assume that a patch has fallen off or has already been removed. Assess the skin thoroughly before administering the medication.
4. When taking a medication history or reconciling medications, specifically ask the patient whether he or she takes any medications in the form of patches, topical creams, or any route other than the oral route.
5. If the dressing or patch is difficult to see (e.g., it is clear), apply a noticeable label to the patch.
6. Document removal of the patch or medication on the medication administration record or computer record.

Nasal Instillation. Patients with nasal sinus alterations may receive medications by spray, drops, or tampons (Box

33-17). The most commonly administered form of nasal **instillation** (administration of a liquid) is a decongestant spray or drops, which are used to relieve symptoms of sinus congestion and colds. Caution patients to avoid abuse of medications because overuse can lead to a rebound effect in which the nasal congestion worsens. When excess decongestant solution is swallowed, serious systemic effects can develop, especially in children. Saline drops are safer as a decongestant for children than nasal preparations that contain sympathomimetics (e.g., Afrin or Neo-Synephrine).

Self-administering sprays is easier because the patient can control the spray and inhale as it enters the nasal passages. For patients who use nasal sprays repeatedly, check the nares for irritation. Position patients to permit the medication to reach the affected sinus.

Eye Instillation. Common eye medications used by patients are eye drops and ointments, including OTC

► BOX 33-16 Procedural Guideline

Giving Medications Through a Nasogastric Tube, Intestinal Tube, Gastrostomy Tube, or Small-Bore Feeding Tube

Delegation Considerations:

The administration of medications through a nasogastric tube, intestinal tube, gastrostomy tube, or smallbore feeding tube cannot be delegated. Instruct unregulated care providers to report the occurrence of side effects immediately.

Equipment:

- 60 mL syringe (catheter tip for large-bore tubes, Luer-Lok tip for small-bore tubes)
- Gastric pH test strips (scale of 0.0 to 11.0 or 14.0 preferred)
- Graduated container
- Water
- Medication to be administered
- Pill crusher, if medication is in tablet form
- Medication administration record
- Clean gloves

Procedure:

1. Check the accuracy and completeness of each medication administration record against the prescriber's written medication order.
- Check the patient's name, the drug name and dosage, and the route and time of administration.
2. Investigate and, if possible, use alternative routes of medication administration (e.g., intravenous, transdermal, rectal).
3. Avoid complicated medication regimens that frequently interrupt enteral feedings.
4. Prepare medication (see Skill 33-1, Steps 7A–G and M–O). Check the label of the medication with the medication administration record three times.
5. Avoid giving elixirs or medications that have a pH of less than 4.
6. Never add medications directly to a feeding tube. Before administering a medication, determine if it needs to be given on an empty stomach or if it is compatible with the enteral feeding. The amount of time the enteral feeding needs to be held before administration varies with the medication. Verify the amount of the time that you hold a feeding with agency policy or with a pharmacist.
7. Verify tube placement before administering medications (see Chapter 42).
8. Administer medications in a liquid form (suspension, elixir, or solution) when possible to prevent tube obstruction.

9. Before crushing tablets, ensure they are crushable. Buccal, sublingual, enteric-coated, or sustained-release medications cannot be crushed. Read medication labels carefully before crushing a tablet or opening a capsule.
10. Take medications to the patient at the correct time and perform hand hygiene.
11. Identify the patient by using at least two patient identifiers. Compare the patient's name and one other identifier (e.g., the hospital identification number) on the identification bracelet with the medication administration record. Ask the patient to state his or her name if possible, for a third identifier.
12. Compare the labels on the medications against the medication administration record one more time at the patient's bedside.
13. Explain the procedure and the medications to the patient.
14. Dissolve crushed tablets, gelatin capsules, and powders in 15 to 30 mL of warm water. Dissolve each medication separately.
15. Do not give whole or undissolved medications through the feeding tube.
16. Put on clean, disposable gloves.
17. Verify the placement of any tube that enters the mouth or nose by using pH testing (see Chapter 42).
18. Assess gastric residual (see Chapter 42).
19. Draw up medication in syringe. Do not mix medications together.
20. Connect the syringe with medication to a nasogastric tube, G-tube, J-tube, or small-bore feeding tube. Do not use the pigtail vent for irrigation or instillation of fluid.
21. Administer medication either by pushing the medication through the tube by depressing the plunger of the syringe or by allowing the medication to flow into the body freely by using gravity. Administer each medication separately.
22. Flush the tube with 15 to 30 mL of warm water between each medication. Unless contraindicated, the total amount of liquid volume administered to the patient is approximately 60 mL.
23. After giving all the medications, flush the tube once more with 30 to 60 mL of warm water.
24. Remove gloves and perform hand hygiene.
25. Document administration of medications on the medication administration record.
26. Continually evaluate the patient's response to medication therapy. If the desired effect is not achieved, a different medication or a different route of administration may be indicated because of problems with the drug bioavailability when given by the enteral route.

Adapted from Jordan, S., Griffiths, H., & Griffin, R. (2003). Administration of medicines. II. Pharmacology. *Nursing Standard*, 18(3), 45–55.

preparations, such as artificial tears and vasoconstrictors (e.g., Visine and Murine). Many patients receive prescribed **ophthalmic** medications for eye conditions, such as glaucoma, and after cataract extraction. In older adults, the ease with which eye medications can be self-administered can be affected by gerontological changes, including poor vision, hand tremors, and difficulty grasping or manipulating containers. Instruct patients and their family members about the proper techniques for administering eye medications (Skill 33-2). Determine the ability of the patient and the patient's family members to administer the eye medication by demonstrating the procedure. Showing patients each step of the procedure for instilling

eye drops can improve their compliance. Follow these principles when administering eye medications:

- The cornea of the eye is richly supplied with pain fibres and thus is very sensitive to anything applied to it. Avoid instilling any form of eye medication directly onto the cornea.
- The risk of transmitting infection from one eye to the other is high. Avoid touching the eyelids or other eye structures with eyedroppers or ointment tubes.
- Use eye medication only for the patient's affected eye.
- Never allow a patient to use another patient's eye medications.

Text continued on p. 704

► BOX 33-17 Procedural Guideline

Administering Nasal Instillations

Delegation Considerations:

The administration of nasal drops and ointments cannot be delegated. Instruct unregulated care providers to report the occurrence of medication side effects immediately.

Equipment:

- Prepared medication with a clean dropper or spray container
- Facial tissue
- Small pillow (optional)
- Washcloth (optional)
- Clean, disposable gloves (if patient has extensive nasal drainage)
- Medication administration record
- Penlight (to inspect nares; if ointment is to be applied to a specific lesion inside the nares)

Procedure:

1. Check the accuracy and completeness of each medication administration record (MAR) or computer printout against the prescriber's original medication order. Check the patient's name and the medication name, dosage, route, and time for administration. Copy or rewrite any portion of the MAR that is difficult to read.
2. If nasal drops are to be administered, refer to the medical record to determine which sinus is affected, so that you can position the patient appropriately for drug instillation.
3. Assess the patient's medical history (e.g., cardiovascular disease, hyperthyroidism). Medical conditions can contraindicate the use of decongestants that stimulate the central nervous system. Side effects may occur, such as transient hypertension, tachycardia, palpitations, and headache.
4. List the patient's food and drug allergies on each page of the MAR and prominently display the allergies on the patient's medical record as per agency policy. Determine whether the patient has any allergies to medications delivered via nasal instillation.
5. Review the physician's order, including the patient's name and the medication name, dosage, route, time of administration, and indication.
6. Take the medication to the patient at the correct time and perform hand hygiene. Using a penlight, inspect the condition of the nose and sinuses. Palpate sinuses for tenderness.
7. Assess the patient's knowledge regarding the use of nasal instillations and the technique for instillation, and determine whether the patient is willing to learn self-administration.
8. Prepare the medication (see Skill 33-1, Steps 7A–G, M–O). Ensure you compare the label of the medication against the MAR at least two times while preparing the medications.
9. Identify the patient by using at least two identifiers. Compare the patient's name and one other identifier (e.g., the hospital identification number) on the MAR, computer printout, or computer screen with information on the patient's identification bracelet. Ask the patient to state his or her name if possible, for a third identifier.
10. Compare the MAR with the medication labels at the patient's bedside.
11. Explain the procedure to the patient regarding the positioning and the sensations to expect, such as a burning or stinging of the mucosa, or a choking sensation as the medication trickles into the throat.
12. Arrange the supplies and medications at the bedside. Put on gloves if the patient has nasal drainage.
13. Gently roll or shake the medication container.
14. Instruct the patient to clear or blow the nose gently unless contraindicated (e.g., risk of increased intracranial pressure or nosebleeds). Clearing the nose helps to remove mucus and secretions that can block medication distribution.
15. Administer nasal drops:
 - A. Assist the patient to a supine position and position the head properly to facilitate access to the nasal passages.
 - (1) To access the posterior pharynx, tilt the patient's head backward.
 - (2) To access the ethmoid and sphenoid sinuses, tilt the head back over the edge of the bed or place a small pillow under the patient's shoulder and tilt the head back (see Step 15A[2] illustration).
 - (3) To access the frontal and maxillary sinuses, tilt the head back over the edge of the bed or pillow with the head turned toward the side to be treated (see Step 15A[3] illustration). This position will allow the medication to drain into the affected sinus.

Step 15A (2) Position for instilling nose drops into the ethmoid and sphenoid sinuses.

Step 15A (3) Position for instilling nose drops into the frontal and maxillary sinuses.

Continued

► BOX 33-17 Procedural Guideline—cont'd

- B. Support the patient's head with your nondominant hand to prevent the straining of neck muscles.
- C. Instruct the patient to breathe through the mouth, which reduces the chance of aspirating nasal drops into the trachea and lungs.
- D. Hold the dropper 1 cm above the nares to avoid contamination of the dropper. Instill the prescribed number of drops toward midline of the ethmoid bone to facilitate distribution of medication over the nasal mucosa.
- E. Have the patient remain in a supine position for five minutes to prevent premature loss of medication through the nares.
- F. Offer a facial tissue to blot a runny nose, but caution the patient against blowing the nose for several minutes.
16. Assist the patient to a comfortable position after the medication is absorbed.
17. Administering nasal spray:
 - A. Assist the patient to a comfortable high Fowler's position or a sitting position.
 - B. Administer the nasal spray with the patient's head upright. Tipping the opening of the nasal spray container downward will cause the medication to be administered in a stream, not a spray, and will deliver more medication than the prescribed order.
 - C. Offer a facial tissue to blot a runny nose, but caution the patient against blowing the nose for several minutes.
18. Dispose of soiled supplies in the proper container and perform hand hygiene.
19. Document administration of medication on the MAR or in the computer.
20. Observe the patient for the onset of side effects 15 to 30 minutes after administration. Drugs absorbed through mucosa can cause a systemic reaction.
21. Ask whether the patient is able to breathe through the nose after decongestant administration to determine the drug's effectiveness. Sometimes the patient will need to occlude one nostril at a time and breathe deeply.
22. Evaluate the patient's response to the medications at times that correlate with the medication's onset, peak, and duration. Evaluate the patient for both desired effects and adverse effects. Reinspect the condition of the nasal passages between the instillations.
23. Ask the patient to review the risks of overuse of decongestants and methods for administration.
24. Have the patient demonstrate self-medication.

► SKILL 33-2 Administering Ophthalmic Medications

Delegation Considerations

The administration of eye drops and ointments cannot be delegated. Instruct unregulated care providers to report the occurrence of medication side effects, including the potential for visual difficulty, immediately.

Equipment

- Medication bottle with sterile eyedropper, ointment tube, or medicated intraocular disc
- Cotton ball or tissue
- Washbasin filled with warm water and washcloth if eyes have crust or need drainage
- Eye patch and tape (optional)
- Clean gloves
- Medication administration record (MAR) or computer printout

Procedure

STEPS

1. Check the accuracy and completeness of each MAR or computer printout against the prescriber's medication order. Check the patient's name, the medication name and dosage (e.g., number of drops, if a liquid), the eye to be treated (e.g., right, left, or both eyes), and the route and time of administration. Copy or rewrite any portion of the MAR that is difficult to read.
2. Assess the condition of the patient's external eye structures. (This may also be assessed just before drug instillation.)
3. Determine whether the patient has any known allergies to eye medications. Also ask whether the patient has an allergy to latex.
4. Determine whether the patient has any symptoms of visual alterations.
5. Assess the patient's level of consciousness and ability to follow directions.
6. Assess the patient's knowledge regarding medication therapy and the desire to self-administer medication.
7. Assess the patient's ability to manipulate and hold an eye dropper.

RATIONALE

- This assessment provides a baseline to help determine whether the medication causes a local response. The assessment also indicates the need to clean the eye before medication application.
- Certain eye medications act to either decrease or increase these symptoms. Determining the patient's visual alteration status ensures that you are able to recognize a change in patient's condition after the medication is administered.
- A patient who becomes restless or combative during the procedure is at a greater risk of accidental eye injury.

► SKILL 33-2 Administering Ophthalmic Medications—cont'd

8. Prepare medication (see Skill 33-1, Steps 7A–G and M–O): Ensure that you check the label of the medication against the MAR at least two times while preparing the medication.
 9. Take the medication to the patient at the correct time and perform hand hygiene.
 10. Identify the patient by using at least two patient identifiers. Compare the patient's name and one other identifier (e.g., the hospital identification number) on the MAR, computer printout, or computer screen with information on patient's identification bracelet. Ask the patient to state his or her name if possible, for a third identifier.
 11. Compare labels of medications with the MAR or computer printout at the patient's bedside.
 12. Arrange the medication supplies at the bedside and put on clean gloves. If eye drops are stored in the refrigerator, allow them to reach room temperature before instilling them.
 13. Gently roll the container.
 14. Explain the procedure to the patient, including the positioning and sensations to expect, such as burning or stinging.
 15. Ask the patient to lie supine or to sit back in a chair with the head slightly hyperextended.
 16. If crusts or drainage are present along the eyelid margins or the inner canthus, gently wash them away. Soak any crusts that are dried and difficult to remove by applying a damp washcloth or cotton ball over the eye for a few minutes. Always wipe from the inner canthus to the outer canthus.
 17. Hold a cotton ball or clean tissue in your nondominant hand.
 18. With the tissue or cotton resting below the lower lid, gently press downward with your thumb or forefinger against the bony orbit.
 19. Ask the patient to look at the ceiling and explain the steps to the patient.
 - A. Instill the eye drops:
 - (1) With your dominant hand resting on the patient's forehead, hold the filled medication eyedropper or the ophthalmic solution approximately 1–2 cm above the conjunctival sac (see Step 19A[1] illustration).
 - (2) Instill the prescribed number of medication drops into the conjunctival sac.
 - (3) If the patient blinks or closes the eye, or if the drops land on the outer lid margins, repeat the procedure.
 - (4) After instilling the drops, ask the patient to close the eye gently.
 - (5) When administering medications that cause systemic effects, apply gentle pressure with your finger and a clean tissue on the patient's nasolacrimal duct for 30–60 seconds.
 - B. Instill eye ointment:
 - (1) Ask the patient to look at the ceiling.
- The use of gloves reduces the transmission of microorganisms and follows standards to prevent accidental exposure to body fluids. Warming the eye drops reduces irritation to the eye.
 - Rolling the container ensures the medication is mixed before administration. Shaking the bottle causes bubbles, which makes medication administration difficult.
 - This position provides easy access to the eye for medication instillation and minimizes drainage of medication through the tear duct.
 - Crusts or drainage harbours microorganisms. Soaking allows easy removal of the crusts and prevents pressure from being applied directly over the eye. Cleansing from the inner canthus to the outer canthus avoids entrance of microorganisms into the lacrimal duct.
 - Cotton or tissue absorbs the medication that escapes the eye.
 - This technique exposes the lower conjunctival sac. Retraction against the bony orbit prevents pressure and trauma to the eyeball and prevents your fingers from touching the eye.
 - When the patient looks toward the ceiling, this action retracts the sensitive cornea up and away from the conjunctival sac and reduces stimulation of the blink reflex.
 - This technique helps to prevent accidental contact of the eyedropper with eye structures, thus reducing risk of both injury to the eye and transfer of infection to dropper. Ophthalmic medications are sterile.
 - The conjunctival sac normally holds 1 or 2 drops, which provides even distribution of medication across the eye.
 - The patient obtains the therapeutic effect of the drug only when the eyedrops enter the conjunctival sac.
 - Closing the eye helps to distribute the medication. Squinting or squeezing of eyelids forces medication from the conjunctival sac (VisionRx, 2005).
 - This action prevents both the overflow of medication into the nasal cavity.
 - This action retracts the sensitive cornea up and away from the conjunctival sac and reduces stimulation of the blink reflex.

Continued

► **SKILL 33-2 Administering Ophthalmic Medications—cont'd**

video

- (2) Hold the ointment applicator above the lower lid margin, apply a thin stream of ointment evenly along the inner edge of the lower eyelid on the conjunctiva (see Step 19B [2] illustration) from the inner canthus to outer canthus.

Step 19A (1) Hold the eyedropper above the conjunctival sac.

- (3) Have the patient close the eye and use a cotton ball to rub the lid lightly in a circular motion, if rubbing is not contraindicated.

C. Intraocular disc

(1) Application:

- Open the package containing the disc. Gently press your fingertip against the disc so that it adheres to your finger. Position the convex side of the disc on your fingertip (see Step 19C[1][a] illustration).
- With your other hand, gently pull the patient's lower eyelid away from the eye. Ask the patient to look up.
- Place the disc in the conjunctival sac, so that it floats on the sclera between the iris and the lower eyelid (see Step 19C[1][c] illustration).

Step 19C(1)(a) Gently position the convex side of the disc against your fingertips.

- (d) Pull the patient's lower eyelid out and over the disc (see Step 19C[1][d] illustration).

Step 19C(1)(d) Gently pull the lower eyelid over the disc.

- This technique distributes the medication evenly across the eye and lid margin.

Step 19B (2) Apply ointment along the lower eyelid.

- This action further distributes the medication without traumatizing the eye.

- These actions allow you to inspect the disc for damage or deformity.

- This action prepares the conjunctival sac for receiving the medicated disc.
- This placement ensures delivery of the medication.

Step 19C(1)(c) Place the disc in the conjunctival sac between the iris and the lower eyelid.

- This action ensures accurate medication delivery.

► SKILL 33-2 Administering Ophthalmic Medications—cont'd

Critical Decision Point: You should not be able to see the disc at this time. If you can see the disc, repeat step 19C(1)d.

(2) Removal:

- (a) Perform hand hygiene and put on gloves.
- (b) Explain the procedure to the patient.
- (c) Gently pull on the patient's lower eyelid to expose the intraocular disc.
- (d) Using your forefinger and thumb of the opposite hand, pinch the disc and lift it out of the patient's eye (see Step 19C(2)[d] illustration).

Step 19C(2)(d) Carefully pinch the disc to remove it from the patient's eye.

20. If excess medication is on the eyelid, gently wipe it from the inner canthus to outer canthus.
 21. If the patient wears an eye patch, apply a clean patch by placing it over the affected eye so that the entire eye is covered. Tape securely without applying pressure to eye.
- Wiping away of excess medication promotes the patient's comfort and prevents trauma to eye (Vision Rx, 2005).
 - A clean eye patch reduces the chance of infection.

Critical Decision Point: If the patient receives more than one eye medication to the same eye at the same time, wait at least 5 minutes before administering the next medication to avoid interaction between medications (Vision Rx, 2005).

22. If the patient receives eye medication to both eyes at the same time, use a different tissue or cotton ball for each eye.
 23. Remove gloves, dispose of soiled supplies in proper receptacle, and perform hand hygiene.
 24. Note the patient's response to instillation; ask whether the patient felt any discomfort.
 25. Observe the patient's response to the medication by assessing any visual changes and noting any side effects.
 26. Ask the patient to discuss the medication's purpose, action, side effects, and the technique of administration.
 27. Have the patient demonstrate self-administration of the next dose.
- The use of separate tissues or cotton balls prevents cross-contamination between eyes.
 - The patient's response determines whether the procedure was performed correctly and safely and whether the patient is experiencing adverse effects of the medication.

Unexpected Outcomes

Inability of patient to instill drops without supervision

Signs of reaction to medication, such as allergic reaction (e.g., tearing, reddened sclera) or systemic response (e.g., bradycardia)

Related Interventions

- Reinforce your teaching and allow the patient to self-administer drops as often as possible to enhance confidence.
- If the patient cannot self-administer drops, teach others, such as family members, to instill drops into the patient's eye.
- Follow the institutional policy or guidelines for the reporting of adverse or allergic reaction to medications.
- Notify the patient's health care provider immediately, and withhold further administration of the medication.
- Add information about the allergy to the patient's medical record, according to agency policy.

Recording and Reporting

- Document on the MAR or the computer record the medication, concentration, number of drops, time of administration, and the eye (left, right, or both) that received medication.
- Record the appearance of the eye in the nurses' notes.

Home Care Considerations

- Patients with chronic health care problems should consult with their health care provider before they use over-the-counter eye medication.
- When they use eye drops at home, patients should not share medications with other family members because the risk of infection transmission is high.

Intraocular Administration. Some medications are administered intraocularly (see Skill 33-2). Intraocular medications resemble a contact lens. Place the medication into the conjunctival sac, where it remains in place for up to one week. Medications such as pilocarpine are administered this way. You will need to teach the patient about monitoring for adverse reactions to the disc. Patients will also need to be taught how to insert and remove the disc.

Ear Instillation. Internal ear structures are very sensitive to temperature extremes. Failure to instill ear drops or irrigating fluid at room temperature may cause vertigo (severe

dizziness) or nausea. Although the structures of the outer ear are not sterile, sterile drops and solutions are used in case the eardrum is ruptured. The entrance of nonsterile solutions into middle ear structures can result in infection. If the patient has ear drainage, assess the ear to ensure the patient does not have a ruptured eardrum. Never occlude the ear canal with the dropper or an irrigating syringe. Forcing medication into an occluded ear canal creates pressure that will injure the eardrum. Box 33-18 provides guidelines for administering ear drops and ear irrigations and describes the differences in straightening the ear canal for children and adults.

► BOX 33-18 Procedural Guideline

Administering Ear Medications

Delegation Considerations:

The administration of ear medications cannot be delegated. Instruct unregulated care providers about the potential side effects of ear medications and the need to report their occurrence immediately.

Equipment:

- Medication administration record (MAR)
- Clean gloves if patient has drainage from the ear
- Medication bottle with dropper, cotton-tipped applicator, and cotton ball (optional) if ear drops are being administered
- Irrigating syringe, kidney-shaped basin, and towel if ear is to be irrigated

Procedure:

1. Check the accuracy and completeness of each MAR or computer printout against the prescriber's original medication order. Check the patient's name and the medication name, dosage, route, and time for administration. Copy or rewrite any portion of the MAR that is difficult to read.
2. Prepare the medication. Ensure that you compare the label of the medication against the MAR at least two times during the medication preparation.
3. Take the medication to the patient at the correct time and perform hand hygiene. Put on gloves if drainage is present.
4. Identify the patient by using at least two patient identifiers. Compare the patient's name and one other identifier (e.g., the hospital identification number) on the MAR, computer printout, or computer screen with information on the patient's identification bracelet. Ask the patient to state his or her name if possible, for a third identifier.
5. Compare the label on the medication with the MAR one more time at the patient's bedside. *This is the third accuracy check.*
6. Explain the procedure to the patient regarding positioning and the sensations to expect, such as hearing bubbling or feeling water in the ear as medication trickles into the ear.
7. Teach the patient about the medication.
8. Administer the ear drops:
 - A. Have the patient assume a side-lying position (if this position is not contraindicated by patient's condition) with the ear to be treated facing up. Alternatively, the patient may sit in a chair or at the bedside.
 - B. Perform hand hygiene. Put on gloves if drainage is present.
 - C. Straighten the ear canal by pulling the auricle down and back (for children under three years of age) or upward and outward (for adults).
 - D. Hold the dropper 1 cm above the ear canal and instill the prescribed drops (see Step 8D illustration).
 - E. Ask the patient to remain in a side-lying position for two to three minutes. Apply gentle massage or pressure to the tragus of the ear with your finger unless contraindicated due to pain.
 - F. If a cotton ball is needed, place the cotton ball into the outermost part of the ear canal. Do not press cotton deep into the canal. Remove cotton after 15 minutes.
9. Administer ear irrigations:
 - A. Assess the tympanic membrane or review the medical record for a history of eardrum perforation, which would contraindicate ear irrigation.
 - B. Assist the patient in assuming a sitting or lying position with the head tilted or turned toward the affected ear. Place a towel under the patient's head and shoulder and have the patient hold a kidney-shaped basin under the affected ear.
 - C. Perform hand hygiene. Put on gloves if drainage is present.
 - D. Fill the irrigating syringe with approximately 50 mL of the solution.
 - E. Gently grasp the auricle and straighten the ear canal by pulling it down and back (for children under three years of age) or upward and outward (for children four years of age and older and adults).
 - F. Slowly instill the irrigating solution by holding the tip of the syringe 1 cm above the opening of the ear canal. Allow the fluid to drain out during instillation. Continue until the canal is clean or until all solution is used.
10. Clean the work area and put the medication supplies away.
11. Remove gloves and perform hand hygiene.
12. Document medication administration on the MAR or computer record.
13. Evaluate the patient's response to the medication.

Step 8D Placing ear drop in ear.

The external ear structures of children differ from those of adults. When instilling drops or irrigating solutions, you must first straighten the ear canal. In infants and young children, straighten the cartilaginous canal by grasping the auricle of the ear and pulling it gently down and backward. In adults, the ear canal is longer and composed of underlying bone. The adult ear canal is straightened by pulling the auricle upward and outward. Failure to straighten the canal properly may prevent medicinal solutions from reaching the deeper external ear structures.

Vaginal Instillation. Vaginal medications are available as suppositories, foam, jellies, and creams. Suppositories are individually packaged in foil wrappers and are sometimes stored in a refrigerator to prevent the solid, oval-shaped suppositories from melting. After a suppository is inserted into the vaginal cavity, body temperature causes it to melt and be distributed and absorbed. Foam, jellies, and creams are administered with an applicator inserter (Box 33-19). Give a suppository with a gloved hand in accordance with standard precautions and routine practices (see Chapter 32). Patients often prefer administering their own vaginal medications, which requires privacy. After instillation of the medication, a patient may wish to wear a perineal pad to collect the

drainage. Because vaginal medications are often given to treat infection, the discharge may be foul smelling. Follow aseptic techniques and offer the patient frequent opportunities to maintain her perineal hygiene (see Chapter 37).

Rectal Instillation. Rectal suppositories are thinner and more bullet-shaped than vaginal suppositories. The rounded end prevents anal trauma during insertion. Rectal suppositories contain medications that exert local effects, such as promoting defecation, or systemic effects, such as reducing nausea. Rectal suppositories are usually stored in the refrigerator until administered.

During administration, place the suppository past the internal anal sphincter and against the rectal mucosa (Box 33-20). Otherwise, the suppository may be expelled before it can dissolve and be absorbed into the mucosa. With practice, you learn to recognize the sensation of the sphincter relaxing around the finger. Do not force the suppository into a mass of fecal material. If necessary, clear the rectum with a small cleansing enema before inserting a suppository.

Administering Medications by Inhalation

Medications administered by hand-held inhalers are dispersed through an aerosol spray, mist, or powder that penetrates the

► BOX 33-19 Procedural Guideline

Administering Vaginal Medications

Delegation Considerations:

The administration of medications by the vaginal route cannot be delegated. Instruct unregulated care providers to report new or increased vaginal discharge or bleeding and occurrence of potential side effects of the medications immediately.

Equipment:

- Vaginal cream, foam, jelly, or suppository, or irrigating solution with applicator (if required)
- Clean, disposable gloves
- Towels, or a washcloth, or both
- Paper towels
- Perineal pad
- Drape or sheet
- Water-soluble lubricating jelly
- Medication administration record (MAR) or computer printout

Procedure:

1. Check the accuracy and completeness of each MAR or computer printout against the prescriber's original medication order. Check the patient's name and the medication name, form (cream, foam, jelly, or suppository), route, dosage, time of administration, and drug indication.
2. Review the patient's history of allergies, including allergies to latex. Prepare the medication (see Skill 33-1, Steps 7A–G and M–O). Compare the label of the medication with the MAR two times while preparing the medication.
3. Take the medication to the patient at the correct time and perform hand hygiene.
4. Identify the patient by using at least two patient identifiers. Compare the patient's name and one other identifier (e.g., the hospital identification number) on the MAR, computer printout, or computer screen with information on the patient's identification bracelet. Ask the patient to state his or her name if possible, for a third identifier.
5. Allow the patient to empty or attempt to empty her bladder before administration of vaginal medication. To facilitate adequate absorption, the patient needs to lie quietly for at least 10 minutes.
6. Compare the label on the medication with the MAR one more time at the patient's bedside.
7. Teach the patient about the medication. Explain to the patient the procedure for positioning and the sensations she can expect, such as feelings of moisture or wetness in the vaginal area. Assess the patient's ability to manipulate the applicator or suppository and to position herself to insert the medication. Explain the procedure to the patient. If the patient plans to self-administer the medication, be specific in your explanation.
8. Close the room curtain or door and arrange the supplies at the bedside.
9. Assist the patient to lie in a dorsal recumbent position. This position provides full exposure and easy access to the vaginal canal and allows the suppository to dissolve without escaping through an orifice.
10. Put on clean, disposable gloves.
11. Keep the abdomen and lower extremities draped.
12. Ensure the lighting is adequate to visualize the vaginal opening. Inspect the condition of external genitalia and the vaginal canal, noting the appearance of any discharge. Clean the area with a towel or washcloth if necessary.
13. Insert the vaginal suppository:
 - A. Remove the suppository from its foil wrapper. Apply a liberal amount of sterile water-based lubricating jelly to the smooth or rounded end of the suppository. Lubricate the gloved index finger of your dominant hand.
 - B. With your nondominant gloved hand, expose the vaginal orifice by gently retracting the labial folds.
 - C. With your dominant gloved hand, gently insert the rounded end of the suppository along the posterior wall of the vaginal

Continued

► BOX 33-19 Procedural Guideline—cont'd

Step 13C Insertion of a suppository into the vaginal canal.

canal for the entire length of your finger (7.5 to 10 cm) to ensure equal distribution of the medication along the walls of the vaginal cavity (see Step 13C illustration).

D. Withdraw your finger and wipe any remaining lubricant from around the orifice and labia.

14. Administer the cream or foam:

A. Fill the cream or foam applicator, as described on the package directions.

B. With your nondominant gloved hand, expose the vaginal orifice by gently retracting the labial folds.

C. With your dominant gloved hand, insert the applicator approximately 5 to 7.5 cm. Push the applicator plunger to deposit the medication into the vagina to allow equal distribution of medication (see Step 14C illustration).

Step 14C Instillation of medication in the vaginal canal.

D. Withdraw the applicator and place it on a paper towel. Wipe residual cream from the labia or vaginal orifice.

15. Dispose of supplies, remove gloves, and perform hand hygiene.

16. Instruct the patient to remain on her back for at least 10 minutes.

17. Document the medication administration on the MAR or computer record.

18. If the applicator was used, wear gloves to wash it with soap and warm water, rinse, and store for future use.

19. Offer the patient a perineal pad when she resumes ambulation to prevent vaginal discharge from spreading to clothing.

20. Inspect the appearance of discharge from the vaginal canal and the condition of external genitalia between applications to evaluate the medication's effectiveness.

lung airways. The alveolocapillary network absorbs medications rapidly. **Metered-dose inhalers (MDIs)**, dry powder inhalers (DPIs), and slow-stream inhaler devices usually produce local effects, such as bronchodilatation; however, some medications can lead to serious systemic side effects.

Patients who receive medications by inhalation frequently have chronic respiratory disease, such as chronic asthma, emphysema, or bronchitis. Medications given by inhalation provide these patients with control of their airway obstruction. Inhaled medications are often described as “rescue” or “maintenance” medications. Rescue medications are short-acting medications that are taken for immediate relief of acute respiratory distress. Maintenance inhalers are used on a daily scheduled basis to prevent acute respiratory distress. The effects of maintenance inhalers start within hours of administration and last for a longer period of time than rescue inhalers. Because these patients depend on these medications for disease control, they must learn about the inhalers and how to administer them safely (Skill 33-3). If a patient uses more than one type of inhaler, the bronchodilator is given first.

A metered-dose inhaler (MDI) delivers a measured dose of medication with each push of the canister. Chemical propellants (e.g., hydrofluorocarbons) push the medication out of the

MDI. MDIs are either squeeze-and-breathe inhalers or inhalers activated by the patient's breath. The squeeze-and-breathe MDI requires the application of approximately 2 to 5 kg of pressure to the top of the canister to administer the medication. To use this type of MDI, the patient must have hand strength, which often diminishes as a result of aging or the effects of chronic respiratory disease. Lack of sufficient hand strength can restrict the patient's ability to self-administer medication via MDIs. Breath-activated MDIs release the medication when the patient inhales. Release of the medication is dependent on the strength of the patient's breath on inspiration (Capriotti, 2005). The MDI can be used with a spacer to allow the particles of medication to slow down and break into smaller pieces, which improves the drug's absorption in the patient's airway. Spacers are equipped with a face mask when they are used by infants and children younger than four years of age. Spacers are especially helpful for patients who have difficulty coordinating the steps involved in self-administering inhaled medications. When patients do not use their inhalers and spacers correctly, they do not receive the full effect of the medication. Therefore, patient education is essential.

Dry powder inhalers (DPIs) hold dry, powdered medication and create an aerosol when the patient inhales through a

BOX 33-20 Procedural Guideline

Administering Rectal Suppositories

Delegation Considerations:

The administration of medications by the rectal route cannot be delegated. Instruct unregulated care providers to expect and report fecal discharge or a bowel movement and to report the occurrence of potential side effects or medications immediately.

Equipment:

- Rectal suppository
- Water-soluble lubricating jelly
- Clean gloves (two pair)
- Drape or sheet
- Tissue
- Medication administration record (MAR) or computer printout

Procedure:

1. Check the accuracy and completeness of each MAR or computer printout against the prescriber's original medication order. Check the patient's name and the medication name, route, dosage, and time of administration. Copy or rewrite any portion of the MAR that is difficult to read.
2. Review the medical record for information on rectal surgery, bleeding, and for a history of allergies.
3. Prepare medication (see Skill 33-1, Steps 7A–G and M–O). Ensure that you compare the label of the medication with the MAR two times during medication preparation.
4. Take the medication to the patient at the correct time and perform hand hygiene.
5. Identify the patient by using at least two patient identifiers. Compare the patient's name and one other identifier (e.g., the hospital identification number) on the MAR, computer printout, or computer screen with information on the patient's identification bracelet. Ask the patient to state his or her name if possible, for a third identifier.
6. Compare the label of the medication with the MAR or computer printout one more time at the patient's bedside.
7. Teach the patient about the medication. Explain the procedure to the patient regarding the positioning and the sensations to expect, such as feelings of needing to defecate. Ensure that the patient understands the procedure and he or she can self-administer the medication.
8. Close the room curtain or door and arrange supplies at the bedside.
9. Put on clean gloves.
10. Assist the patient in assuming Sims' position to expose the anus and facilitate relaxation of the external anal sphincter. Keep the patient draped with only the anal area exposed.
11. Ensure the lighting is adequate to visualize the anus. Check for evidence of active rectal bleeding. Examine the condition of the

anus externally and palpate the rectal walls to assess for presence of feces, which may interfere with the suppository placement (see Chapter 31). Dispose of gloves in proper receptacle if they are soiled.

12. Put on a new pair of disposable gloves (if previous gloves were discarded).
13. Remove the suppository from its wrapper and lubricate the rounded end (see Step 13 illustration) with a sterile water-soluble lubricating jelly to reduce the friction when the suppository enters the rectal canal. Lubricate the index finger of your dominant hand with a water-soluble lubricant.

14. Ask the patient to take slow deep breaths through the mouth and relax the anal sphincter.
15. Retract the buttocks with your nondominant hand. Insert the suppository gently through the anus, past the internal sphincter and against the rectal wall, 10 cm in adults, 5 cm in children and infants. Apply gentle pressure to hold the buttocks together momentarily if necessary to keep medication in place and to facilitate medication distribution and absorption.
16. Withdraw your finger and wipe the anal area with tissue.
17. Remove gloves and dispose of medication supplies in the appropriate receptacle and perform hand hygiene.
18. Ask the patient to remain flat or on the side for five minutes to prevent expulsion of the suppository.
19. If the suppository contains a laxative or fecal softener, place a call light within the patient's reach.
20. Document medication administration on the MAR or computer record.
21. Evaluate the effectiveness of the medication by observing the patient for a response to the suppository (e.g., bowel movement, relief of nausea) at times that correlate with the medication's onset, peak, and duration.

reservoir that contains a dose of the medication. DPIs require less manual dexterity than MDIs, and because the device is activated by the patient's breath, the patient does not need to coordinate puffs with inhalation, as required when an MDI is used. DPIs do not require use of a spacer; however, the medication inside the DPI may clump if the DPI is used in a humid climate, and some patients cannot inspire at the speed needed to administer the entire dose of the medication.

One important aspect of patient teaching is to help the patient determine when the MDI or DPI is empty and needs to

be replaced. Floating the MDI to determine the amount of medication remaining is no longer recommended because extra propellant may cause buoyancy even if no medication remains in the inhaler. Furthermore, MDIs with hydrofluoroalkanes (HFA) should never be immersed (Capriotti, 2005). Some DPIs have mechanisms that indicate the number of doses remaining; however, these mechanisms are not always accurate. To calculate how long the medication in an MDI or DPI will last, divide the capacity of the canister by the number of doses the patient takes per day. For example, a patient is to take albuterol, a

► SKILL 33-3 Using Metered-Dose or Dry Powder Inhalers

Delegation Considerations

The administration of a metered-dose inhaler (MDI) or dry powder inhaler (DPI) and the supervision of patients who self-administer these medications cannot be delegated to unregulated care providers (UCPs). Instruct UCPs to report changes in the patient's respiratory status, increased coughing, or the occurrence of potential side effects immediately.

Procedure

STEPS

1. Check the accuracy and completeness of each MAR or computer printout against the prescriber's original medication order. Check the patient's name and the medication name, route, dosage, and time of administration. Copy or rewrite any portion of the MAR that is difficult to read.
2. Assess the patient's respiratory pattern, auscultate the patient's breath sounds.
3. Assess the patient's ability to hold, manipulate, and depress the canister. Assess the patient's strength of inhalation.
4. Assess the patient's readiness to learn: for example, whether the patient asks questions about the medication, disease, or complications; requests education in use of inhaler; is mentally alert; participates in self-care.
5. Assess the patient's ability to learn: the patient should not be fatigued, in pain, or in respiratory distress; assess the patient's level of understanding of technical terms.
6. Assess the patient's knowledge and understanding of the disease and the purpose and action of the prescribed medications.
7. Determine the medication schedule and the number of inhalations prescribed for each dose.
8. Prepare the medication (see Skill 33-1, Steps 7A–G and M–O). Ensure that you compare the label of the medication with the MAR two times during medication preparation.
9. Identify the patient by using at least two patient identifiers. Compare the patient's name and one other identifier (e.g., the hospital identification number) on the MAR, computer printout, or computer screen with information on the patient's identification bracelet. Ask the patient to state his or her name if possible, for a third identifier.
10. Compare the label on medications with the MAR one more time at the patient's bedside.
11. Instruct the patient in a comfortable environment by sitting in a chair in the hospital room or by sitting at a kitchen table in the patient's home.
12. Provide adequate time for the teaching session.
13. Perform hand hygiene and arrange the equipment needed.
14. Allow the patient an opportunity to manipulate the inhaler, the canister, and the spacer device. Explain and demonstrate how the canister fits into the inhaler.

Equipment

- MDI or DPI
- Spacer (optional with MDI)
- Facial tissues (optional)
- Washbasin or sink with warm water
- Paper towel
- Medication administration record (MAR) or computer printout

RATIONALE

- Assessment of the patient's respiratory pattern establishes the baseline of airway status for comparison during and after treatment.
- Any impairment in the ability to grasp, to breathe, or to coordinate movements interferes with the patient's ability to use the MDI or DPI correctly.
- The patient's readiness to learn affects the ability to understand explanations and actively participate in the learning process (Bastable, 2003).
- The patient's mental or physical limitations affect the ability to learn and the methods you can use for instruction (Bastable, 2003).
- Knowledge of disease is essential for the patient to understand the proper use of the inhaler.
- The medication schedule influences the explanations you provide for use of inhaler.
- The patient will be more likely to remain receptive to education if he or she is in a comfortable environment (Bastable, 2003).
- Manipulating the various items facilitates the patient's familiarity with the equipment.

Critical Decision Point: If the patient is using an MDI with or without a spacer and the inhaler is new or has not been used for several days, push a "test spray" into the air (MayoClinic.com, 2007). A test spray is not needed for a DPI.

15. Explain to the patient what a metered dose is and warn the patient about overuse of the inhaler, including medication side effects.
16. Explain the steps for administering squeeze-and-breathe inhaled dose of medication of MDI (demonstrate steps when possible):
 - A. Insert the MDI canister into the holder.
 - B. Remove the mouthpiece cover from the inhaler.
 - C. Shake the inhaler vigorously five or six times.
- The patient must not arbitrarily administer excessive inhalations because of the risk of serious side effects. If medication is given in recommended doses, side effects are uncommon.
- Use of simple, step-by-step explanations allows the patient to ask questions at any point during the procedure.
- Shaking the inhaler ensures that fine particles are aerosolized.

► SKILL 33-3 Using Metered-Dose or Dry Powder Inhalers—cont'd

- D. Have the patient take a deep breath and exhale.
- E. Instruct the patient to position the inhaler in one of two ways.
- (1) Close the mouth around the MDI with the opening toward the back of the throat (see Step 17E(1) illustration).
 - (2) Position the device 2–4 cm in front of the mouth (see Step 17E(2) illustration).

Step 17E (1) The patient opens lips and places inhaler in mouth with opening toward back of throat.

- F. With the inhaler properly positioned, have patient hold the inhaler with thumb at the mouthpiece and the index finger and middle finger at the top. This arrangement is called a three-point or lateral hand position.
- G. Instruct the patient to tilt the head back slightly and inhale slowly and deeply through the mouth for 3–5 seconds while depressing the canister fully.
- H. Instruct the patient to hold the breath for approximately 10 seconds.
- I. Instruct the patient to remove the MDI from the mouth and to exhale through pursed lips.
17. Explain the steps to administer MDI by using a spacer, such as an AeroChamber (demonstrate when possible):
- A. Remove the mouthpiece cover from the MDI and the mouthpiece of the spacer. Inspect the spacer for foreign objects. If the spacer has a valve, ensure the valve is intact.
 - B. Insert the MDI into the end of the spacer.
- C. Shake the inhaler vigorously five or six times.
- D. Have the patient exhale completely before closing the mouth around the mouthpiece of the spacer. Avoid covering small exhalation slots with the lips (see Step 18D illustration).

Step 18D Have the patient place the mouthpiece in the mouth and close the lips, being careful to keep the exhalation slots exposed.

- A deep breath followed by an exhalation empties the lungs and prepares the patient's airway to receive the medication.
- This position directs the aerosol spray toward the airway. Positioning the mouthpiece in front of mouth is considered the best way to deliver the medication.

Step 17E(2) The patient positions the mouthpiece 2 to 4 cm away from the mouth. This placement is considered the best way to deliver the medication.

- MDIs work best when patients use a three-point or lateral hand position to activate the canister.
- Medication is distributed to airways during inhalation. Inhalation through the mouth rather than the nose draws medication more effectively into airways.
- Holding the breath allows tiny drops of aerosol spray to reach the deeper branches of the airways.
- Using pursed lips keeps the small airways open during exhalation.
- The spacer traps medication released from the MDI; the patient then inhales the drug from the device. These devices break up and slow down the medication particles, enhancing the amount of medication received by the patient (Vella & Grech, 2005).
- Shaking the enhaler ensures the fine particles are aerosolized.

► SKILL 33-3 Using Metered-Dose or Dry Powder Inhalers—cont'd

- E. Have the patient depress the medication canister, spraying one puff into the spacer.
 - F. Instruct the patient to inhale deeply and slowly through the mouth for 3–5 seconds.
 - G. Instruct the patient to hold the breath for 10 seconds.
 - H. Instruct the patient to remove the MDI and spacer before exhaling.
18. Explain the steps to administer DPI or breath-activated MDI (demonstrate when possible):
- A. Remove the cover from the mouthpiece. Do not shake the inhaler.
 - B. Prepare the medication as directed by the manufacturer (e.g., hold the inhaler upright and turn the wheel to the right and then to the left until a click is heard, load the medication pellet, etc.).
 - C. Instruct the patient to exhale away from the inhaler before inhalation.
 - D. Position the mouthpiece between the patient's lips.
 - E. Instruct the patient to inhale deeply and forcefully through the mouth.
 - F. Instruct the patient to hold the breath for 5–10 seconds.
19. Instruct the patient to wait at least 20–30 seconds between inhalations of medications.
- The spacer emits a spray that allows finer particles to be inhaled.
 - Large droplets are retained in the spacer.
 - Deep inhalations maximize the amount of medication that enters the lungs.
 - Holding the breath ensures full medication distribution.
 - Removing the MDI and spacer allows the patient to exhale normally.
 - Preparing the medication properly primes the inhaler to ensure the medication will be delivered to the patient (Capriotti, 2005).
 - Exhaling before using the inhaler prevents loss of powder.
 - Properly positioning the mouthpiece prevents the medication from escaping through the mouth.
 - Deep inhalations create aerosol.
 - Holding the breath ensures full medication distribution.
 - Medications must be inhaled sequentially. The first inhalation opens the airways and reduces inflammation. The second or third inhalation penetrates the deeper airways.

Critical Decision Point: If two medications are to be administered, give the bronchodilator first.

20. Instruct the patient in cleaning the inhaler:
- A. Once a day, the inhaler and its cap should be rinsed in warm running water. The inhaler must be completely dry before use.
 - B. Twice a week, the L-shaped plastic mouthpiece should be washed with mild dishwashing soap and warm water. Rinse and dry well before placing the canister back inside the mouthpiece (Canadian Lung Association, n.d.).
21. Ask whether the patient has any questions.
22. Have the patient explain and demonstrate the steps in the use of an inhaler.
23. Ask the patient to explain the medication schedule, side effects, and when to call health care providers.
24. Ask the patient to calculate how many days the inhaler will last.
25. After the medication has been taken, assess the patient's respiratory status, including the ease of respirations, auscultation of lungs, and the use of pulse oximetry to assess the patient's oxygenation status.
- Accumulation of spray around the mouthpiece can interfere with proper distribution during use.
 - Regular cleaning removes residual medication. Do not place inhalers holding cromolyn, nedocromil, or HFA (hydrofluoroalkane) in water.
 - The patient has an opportunity to clarify misconceptions or misunderstandings.
 - A return demonstration provides feedback for measuring the patient's learning.
 - Reviewing the medication requirements improves the likelihood of compliance with the therapy.
 - This calculation helps the patient to determine when to reorder a prescription.
 - Assessment of the respiratory status determines the status of the patient's breathing pattern and adequacy of ventilation.

Unexpected Outcomes

Need for a bronchodilator more frequently than every 4 hours

Cardiac dysrhythmias, especially in patient receiving β -adrenergics

Inability of patient to self-administer medication properly

Paroxysms of coughing

Related Interventions

- Respiratory problems are indicated. The type of medication and delivery methods need to be reassessed. Notify the health care provider if respiratory status does not improve.
- If the patient experiences symptoms with the dysrhythmias (e.g., lightheadedness, syncope), withhold all further doses of medication and notify the prescriber.
- Explore alternative delivery routes or alternative methods of medication administration.
- Aerosolized particles irritate the posterior pharynx. Notify the prescriber; reassess the type of medication or the delivery method.

► SKILL 33-3 Using Metered-Dose or Dry Powder Inhalers—cont'd

Recording and Reporting

- Document the skills that you taught the patient and the patient's ability to perform these skills.
- Document on the MAR or computer record the medication, time of administration, and number of puffs.
- Report any undesirable effects from the medication.

Home Care Considerations

- Remind patients to carry their prescribed inhalers to use immediately in case of an acute asthma attack.

► BOX 33-21 Preventing Infection During an Injection

- To prevent contamination of the solution, draw the medication from the ampule quickly. Do not allow it to stand open.
- To prevent needle contamination, avoid letting the needle touch a contaminated surface (e.g., the outer edges of the ampoule or vial, the outer surface of the needle cap, your hands, a countertop, a table surface).
- To prevent syringe contamination, avoid touching the length of the plunger or the inner part of the barrel. Keep the tip of the syringe covered with a cap or needle.
- To prepare the skin, wash skin soiled with dirt, drainage, or feces with soap and water and then dry. Use friction and a circular motion to clean the skin with an antiseptic swab. Swab from centre of site and move outward in a 5 cm radius.

β -adrenergic agonist bronchodilator. The ordered dose is two puffs four times a day. The canister has a total of 200 puffs. Complete the following calculations to determine how long the MDI will last:

$$2 \text{ puffs} \times 4 \text{ times a day} = 8 \text{ puffs per day}$$

$$200 \text{ puffs} \div 8 \text{ puffs per day} = 25 \text{ days}$$

The canister in this example will last 25 days. To ensure the patient does not run out of medication, teach the patient to refill the medication prescription at least 7 to 10 days before it is expected to run out (MayoClinic.com, 2007).

Administering Medications by Irrigations

Some medications irrigate or wash out a body cavity and are delivered through a stream of solution. Irrigations most commonly use sterile water, saline, or antiseptic solutions to irrigate the eye, ear, throat, vagina, or urinary tract. Use aseptic technique if the patient has a break in the skin or mucosa. When the cavity to be irrigated is not sterile, as in the case of the ear canal (see Box 33-18) or vagina, use a clean technique. In health care settings, sterile solutions are usually used. Irrigations are used to clean an area, instill a medication, or apply heat or cold to injured tissue.

Administering Parenteral Medications

Parenteral administration of medications is the administration of medications by injection. Parenteral administration is an invasive procedure that must be performed with aseptic techniques (Box 33-21). After a needle pierces the skin, the patient is at risk of infection. Each type of injection requires the application of specific skills to ensure the medication

Figure 33-14 Types of syringes. **A**, Luer-Lok syringe marked in 0.1 (tenths). **B**, Tuberculin syringe marked in 0.01 (hundredths) for doses of less than 1 mL. **C**, Insulin syringe marked in units (100). **D**, Insulin syringe marked in units (50).

reaches the proper location. The effects of a parenterally administered medication develop rapidly, depending on the rate of medication absorption. Always closely observe the patient's response.

Equipment. A variety of syringes and needles are available, each designed to deliver a precise volume of medication to a specific type of tissue. Use your nursing judgement when determining the syringe or needle that will be most effective.

Syringes. Syringes consist of a close-fitting plunger and a cylindrical barrel with a tip designed to fit the hub of a hypodermic needle. Syringes, in general, are classified as being Luer-Lok or non-Luer-Lok. This nomenclature is based on the design of the syringe's tip. Luer-Lok syringes (Figure 33-14, **A**) require special needles, which are twisted onto the tip and lock in place. This design prevents the inadvertent removal of the needle. Non-Luer-Lok syringes (Figure 33-14, **B–D**) require needles that slip onto the tip. In clinical settings, all syringes now have safety devices to prevent needle-stick injuries.

Fill the syringe by aspiration, by pulling the plunger outward while the needle tip remains immersed in the prepared solution. You may handle the outside of the syringe barrel and the handle of the plunger. To maintain sterility, avoid letting any unsterile object touch the tip or the inside of the barrel, the hub, the shaft of the plunger, or the needle (Figure 33-15).

Syringes come in numerous sizes, from 0.5 mL to 60 mL. A 1 to 3 mL syringe is usually adequate for a subcutaneous or

Figure 33-15 Parts of a syringe.

Figure 33-16 Parts of the needle.

intramuscular injection. The use of a syringe larger than 5 mL is unusual for an injection. The larger volume creates discomfort. Instead, use larger syringes to administer certain intravenous medications, to add medications to intravenous solutions, and to irrigate wounds or drainage tubes. Syringes may be prepackaged with a needle attached; however, you may change the needle size depending on the route of administration and the size of the patient.

Insulin syringes (see Figure 33-14, C-D) are available in sizes from 0.3 mL to 1 mL and are calibrated in units. Insulin syringes that hold 0.3 mL are known as low-dose syringes (30 units per 0.3 mL). Most insulin syringes are known as U-100s and are designed to be used with insulin that has a strength of U-100. Each millilitre of U-100 insulin contains 100 units of insulin.

The tuberculin syringe (see Figure 33-14, B) has a long, thin barrel with a preattached thin needle. The syringe is calibrated in sixteenths of a minim and in hundredths of a millilitre and has a capacity of 1 mL. Use a tuberculin syringe to prepare small amounts of medications (e.g., intradermal or subcutaneous injections). A tuberculin syringe is also useful when preparing small, precise doses for infants or young children.

Needles. Needles are packaged in individual sheaths to allow flexibility in choosing the right needle for a patient. Some needles are preattached to standard-sized syringes. Most needles are made of stainless steel and are disposable.

The needle has three parts: the hub, which fits onto the tip of a syringe; the shaft, which connects to the hub; and the bevel, or slanted tip (Figure 33-16). The tip of a needle, or the bevel, is always slanted. The bevel creates a narrow slit when it is injected into tissue.

When the needle is removed, the slit quickly closes to prevent leakage of medication, blood, or serum. Long bevelled tips are sharper and narrower to minimize discomfort to the patient when entering tissue used for subcutaneous or intramuscular (IM) injections.

Figure 33-17 Needles. Top to bottom: 19 gauge, 3.8 cm length; 20 gauge, 2.5 cm length; 21 gauge, 2.5 cm length; 23 gauge, 2.5 cm length; and 25 gauge, 1.6 cm length.

Needles vary in length from 0.6 to 7.6 cm (Figure 33-17). Choose the needle length according to the patient's size and weight and the type of tissue into which the medication is to be injected. In general, a child or slender adult requires a shorter needle. Use longer needles (2.5 to 3.8 cm) for intramuscular injections and use a shorter needle (1 to 1.6 cm) for subcutaneous injections.

Needle diameter is measured by gauge. As the gauge becomes smaller, the needle diameter becomes larger (see Figure 33-17). Gauge selection depends on the viscosity of fluid to be injected or infused. An intramuscular injection usually requires an 18- to 27-gauge needle, depending on the viscosity of the medication. Subcutaneous injections require small-diameter needles, such as a 25-gauge needle. A 26-gauge needle is used for an intradermal injection.

Disposable Injection Units. Disposable, single-dose, prefilled syringes are available for some medications. Ensure that you check the medication and concentration because all prefilled syringes look very similar. When using these syringes, you do not have to prepare medication doses, except perhaps to expel portions of unneeded medications.

The Tubex and Carpuject injection systems include reusable plastic mechanisms that hold prefilled, disposable, sterile cartridge-needle units (Figure 33-18). To prepare these systems, slip the cartridge into the syringe, secure it (by following the package directions), and check for air bubbles in the syringe. Advance the plunger to expel excess medication as you would with a regular syringe. A new type of injection system involves screwing a plungerlike device into the end of a prefilled vial that contains a needle. After the medication is given, safely dispose of the entire unit in a puncture-proof and leakproof receptacle. The design of these injection systems reduces the risk of needle-stick injuries.

Figure 33-18 Disposable injection unit. A, Carpuject syringe and pre-filled sterile cartridge with needle. B, Assembling the Carpuject system. C, Cartridge locks at needle end; plunger screws into opposite end.

Preparing an Injection From an Ampule. Ampules contain single doses of medication in a liquid. Ampules are available in several sizes, from 1 mL to 10 mL or more (Figure 33-19, A). An ampule is made of glass with a constricted neck that must be snapped off to access the medication. A coloured ring around the neck indicates where the ampule is scored to be broken easily. Aspiration of the medication into a syringe (Skill 33-4) is sometimes completed by using a filter needle to prevent small glass fragments from entering the syringe (Stein, 2006). Change the filter needle to an appropriate-sized needle for the actual injection.

Preparing an Injection From a Vial. A vial is a single-dose or multidose container with a rubber seal at the top (see Figure 33-19, B). A metal cap protects the seal until it is ready to be used. Vials contain liquid or dry forms of medications. Medications that are unstable in solution are packaged dry. The vial label specifies the solvent or diluents to be used to dissolve the medication and the amount of diluents needed to prepare a desired medication concentration. Normal saline and sterile distilled water are solutions commonly used to dissolve medications.

Unlike the ampule, the vial is a closed system, and air must be injected into the vial to permit easy withdrawal of the solution. Failure to inject air creates a vacuum within the vial that makes withdrawal difficult (see Skill 33-4). If you are concerned about drawing up parts of the rubber stopper or other particles into the syringe, use a filter needle when preparing medications from vials (Nicoll & Hesby, 2002).

To prepare a powdered medication, draw up the amount of diluents or solvent recommended on the vial's label. Inject the diluent into the vial in the same manner used for injecting air into the vial. Most powdered medications dissolve easily, but you may need to withdraw the needle to mix the contents thoroughly. If this step is needed, remove the needle and gently roll the vial between your hands to dissolve the powdered medication, then reinsert the needle to draw up the dissolved medication. After mixing multidose vials, make a label that records the date and time of the mixing and indicates

► SKILL 33-4 Preparing Injections

Delegation Considerations

The preparation of injections cannot be delegated to unregulated care providers (UCPs).

Equipment

- Medication administration record (MAR) or computer printout
- Medication in an ampule
- Syringe, needle, and filter needle
- Small gauze pad or unopened alcohol swab
- Medication in a vial
- Syringe
- Needles:
 - Blunt-tip vial access cannula (if a needleless system used)
 - Filter needle (if indicated)
 - Needle for drawing up medication (if needed) and needle for injection
- Small gauze pad or alcohol swab
- Diluent (e.g., normal saline or sterile water) (if indicated)

Procedure

STEPS

1. Check the accuracy and completeness of each MAR or computer printout against the prescriber's original medication order. Check the patient's name and the medication name, route, dosage, and time of administration. Copy or rewrite any portion of the MAR that is difficult to read.
2. Review the pertinent information related to the medication, including its action, purpose, side effects, and nursing implications.
3. Assess the patient's body build, muscle size, and weight.
4. Perform hand hygiene and assemble the medication supplies.
5. Check the date of expiration on the medication vial or ampule.
6. Prepare medication (see Skill 33-1, Steps 7A–G and M–O): Ensure that you compare the label of the medication with the MAR at least two times while preparing the medication.
 - A. Ampule preparation
 - (1) Tap the top of the ampule lightly and quickly with your finger until the fluid moves from the neck of the ampule (see Step 6A[1] illustration).

Step 6A(1) Tapping the ampule moves the fluid down the neck of the ampule.

- (2) Place a small gauze pad or an unopened alcohol swab around the neck of the ampule (see Step 6A[2] illustration).

RATIONALE

- The patient's body type determines the type and size of the syringe and the needles for injection.
- Medication potency may increase or decrease when medications are expired.
- Tapping the ampule dislodges any fluid that collects above the neck of the ampule. All solution moves into the lower chamber of the ampule.
- Placing a pad around the neck of the ampule protects your fingers from injury when the glass tip is broken off.

► SKILL 33-4 Preparing Injections—cont'd

- (3) Snap the neck of the ampule quickly and firmly away from the hands (see Step 6A[3] illustration).

Step 6A(2) Gauze pad placed around the neck of the ampule.

- (4) Draw up the medication quickly, using a filter needle long enough to reach the bottom of the ampule.
- (5) Hold the ampule upside down, or set it on a flat surface. Insert the filter needle into the centre of the ampule opening. Do not allow the needle tip or shaft to touch the rim of the ampule.
- (6) Aspirate the medication into the syringe by gently pulling back on the plunger (see Step 6A[6] illustrations).

A

Step 6A(3) Snapping the neck of the ampule away from the hands.

- The injection system is vulnerable to airborne contaminants. The needle must be long enough to access the medication for preparation. Filter needles are used to sift out any fragments of glass (Stein, 2006).
- The broken rim of the ampule is considered contaminated. When the ampule is inverted, the solution dribbles out if the needle tip or shaft touches the rim of the ampule.
- Withdrawal of the plunger creates negative pressure within the syringe barrel, which pulls the fluid into the syringe.

B

Step 6A(6) A, Medication aspirated with the ampule inverted. B, Medication aspirated with the ampule on a flat surface.

- (7) Keep the needle tip under the surface of the liquid. Tip the ampule to bring all fluid within reach of the needle.
- (8) If air bubbles are aspirated, do not expel the air into the ampule.
- (9) To expel excess air bubbles, remove the needle from the ampule. Hold the syringe with the needle pointing up. Tap the side of the syringe to cause the bubbles to rise toward the needle. Draw back slightly on the plunger, then push the plunger upward to eject the air. Do not eject any fluid.
- (10) If the syringe contains excess fluid, dispose of it in a sink. Hold the syringe vertically with the needle tip up and slanted slightly toward the sink. Slowly eject the excess fluid into the sink. Recheck the fluid level in the syringe by holding it vertically.
- Keeping the needle tip under the surface of the liquid prevents the aspiration of air bubbles.
 - Expelling air into the ampule may force fluid out of the ampule, which could lead to loss of the medication.
 - Withdrawing the plunger too far will remove it from the barrel. Holding the syringe vertically allows fluid to settle in the bottom of the barrel. Pulling back on the plunger allows the fluid within the needle to enter the barrel so that fluid is not expelled. Air at the top of the barrel and within the needle is then expelled.
 - Medication is safely dispersed into the sink. The position of the needle allows the medication to be expelled without flowing down the needle shaft. Rechecking the fluid level ensures the proper dose.

Continued

► SKILL 33-4 Preparing Injections—cont'd

- (11) Cover the needle with its safety sheath or cap. Replace the filter needle with a needle or a needleless access device for injection.

B. Vial containing a solution

- (1) Remove the cap covering the top of the unused vial to expose the sterile rubber seal. If a multidose vial has been previously used, the cap has already been removed. Firmly and briskly wipe the surface of the rubber seal with an alcohol swab and allow it to dry.
- (2) Pick up the syringe and remove the needle cap or the cap covering the needleless vial access device (see Step 6B[2] illustration). Pull back on the plunger to draw an amount of air into the syringe equivalent to the volume of medication to be aspirated from the vial.

Step 6B(2) Syringe with needleless adapter.

Critical Decision Point: Some medications require that a filter needle be used when preparing medications from a vial. The same policy is required by some institutions. Check the agency policy to determine whether the use of a filter needle is indicated (Nicoll & Hesby, 2002). If using a filter needle to aspirate the medication, use an appropriately sized needle to administer the medication.

- (3) With the vial on a flat surface, insert the tip of the needle. Ensure the bevelled tip enters first, through the centre of the rubber seal (see Step 6B[3] illustration). Apply pressure to the tip of the needle during insertion.

Step 6B(3) Insert the tip of the needle through the centre of the vial diaphragm (with the vial flat on the table).

- Covering the needle prevents contamination of the needle and minimizes needle-stick injuries. Filter needles cannot be used for injection.
- The vial comes packaged with a seal that cannot be replaced after the cap has been removed. Not all drug manufacturers guarantee that caps of unused vials are sterile. Therefore, seals must be swabbed with alcohol before preparing the medication. Allowing the alcohol to dry prevents the needle from being coated with alcohol, which could mix with the medication.
- Inject air into the vial to prevent the buildup of negative pressure in the vial when aspirating medication.

► SKILL 33-4 Preparing Injections—cont'd

- (4) Inject air into the vial's airspace, holding on to the plunger. Hold the plunger with firm pressure; the plunger may be forced backward by air pressure within the vial.
- (5) Invert the vial while keeping a firm hold on the syringe and plunger (see Step 6B[5] illustration). Hold the vial between your thumb and the middle fingers of your nondominant hand. Grasp the end of the syringe barrel and plunger with the thumb and forefinger of your dominant hand to counteract pressure in the vial.

Step 6B(5) Withdraw fluid with the vial inverted.

- (6) Keep the tip of the needle below the fluid level.
 - (7) Allow air pressure from the vial to fill the syringe gradually with medication. If necessary, pull back slightly on the plunger to obtain the correct amount of solution.
 - (8) When the desired volume of solution is obtained, position the needle into the vial's airspace; tap the side of the syringe barrel carefully to dislodge any air bubbles. Eject any air remaining at the top of the syringe into the vial.
 - (9) Remove the needle from the vial by pulling back on the barrel of the syringe.
- Injecting air before aspirating the fluid creates a vacuum that is needed to allow the medication to flow into the syringe. Injecting air into the vial's airspace prevents the formation of bubbles, which can lead to an inaccurate dose.
 - Inverting the vial allows the fluid to settle in the lower half of the container. Correct positioning of your hands prevents forceful movement of the plunger and permits easy manipulation of the syringe.
 - Keeping the needle tip under the surface of the liquid prevents the aspiration of air.
 - Positive pressure within the vial forces the fluid into the syringe (unless the vial has been used several times).
 - Forcefully striking the barrel while the needle is inserted in the vial may bend the needle. The accumulation of air displaces the medication and can lead to dose errors.
 - Accidentally pulling the plunger instead of the barrel can cause the plunger to separate from the barrel, which can result in the loss of medication.

Continued

SKILL 33-4 Preparing Injections—cont'd

- (10) Hold the syringe at eye level, at a 90-degree angle, to ensure the correct volume has been obtained and no air bubbles are present. Remove any remaining air by tapping the barrel to dislodge the air bubbles (see Step 6B(10) illustration). Draw back slightly on the plunger; then push the plunger upward to eject the air. Do not eject the fluid. Recheck the volume of the medication.

Step 6B(10) Hold the syringe upright and tap the barrel to dislodge air bubbles.

- (11) If medication is to be injected into a patient's tissue, change the needle to one of the appropriate gauge and length according to the route of medication and the patient's size and weight.
- (12) For a multidose vial, make a label that includes the date of mixing, the concentration of the medication per millilitre, and your initials.
- C. Vial containing a powder (reconstituting medications)**
- (1) Remove the cap covering the vial of powdered medication and the cap covering the vial of proper diluent. Firmly wipe both seals with the alcohol swab and allow to dry.
 - (2) Draw up diluent into the syringe following the Steps 6B(2) through 6B(10).
 - (3) Insert the tip of the needle through the centre of the rubber seal on the vial of powdered medication. Inject the diluents into the vial. Remove the needle.
 - (4) Mix the medication thoroughly. Roll the vial in your palms. Do not shake.
 - (5) Reconstituted medication in the vial is ready to be drawn into a new syringe. Read the label carefully to determine the dose after reconstitution.
 - (6) Prepare medication in syringe following Steps 6B(2) through 6B(12).

- Holding the syringe vertically allows fluid to settle in the bottom of the barrel. Pulling back on the plunger allows the fluid within the needle to enter the barrel so that fluid is not expelled. Air at the top of the barrel and within the needle is then expelled.

- Inserting a needle through a rubber stopper may dull the bevelled tip. New needles are sharper. Because no fluid remains along the shaft, the needle will not track medication through the tissues.
- Labelling ensures that future doses will be prepared correctly. Some medications must be discarded after a certain number of days have elapsed since the mixing of the vial.
- Not all drug manufacturers guarantee that caps of unused vials are sterile. Therefore, seals must be swabbed with alcohol before preparing the medication. Allowing the alcohol to dry prevents the needle from being coated with alcohol, which could mix with the medication.
- Drawing up the diluent prepares the diluent for injection into a vial containing powdered medication.
- The diluent begins to dissolve and reconstitute medication.
- Rolling ensures proper dispersal of medication throughout the solution. Shaking produces bubbles.
- After the diluent has been added, the concentration of medication (mg/mL) determines the dose to be given.

Critical Decision Point: Some institutions may require prepared parenteral medications to be verified for accuracy by another nurse. Check the agency policy before administering medication.

► SKILL 33-4 Preparing Injections—cont'd

- Dispose of all soiled supplies. Place broken ampule vials, used vials, and used needles in a puncture-proof and leak-proof container. Clean the medication work area and perform hand hygiene.

Unexpected Outcomes

Air bubbles remaining in syringe

Incorrect dose prepared

- Proper disposal of glass and needle prevents accidental injury to staff and controls the transmission of infection.

Related Interventions

- Expel air from the syringe and add medication to the syringe until the correct dose is prepared.
- Discard the prepared dose and prepare the corrected new dose.

Figure 33-20 Mixing medications from two vials. A, Injecting air into vial A. B, Injecting air into vial B and withdrawing the dose. C, Withdrawing medication from vial A; the two medications are now mixed.

the concentration of medication per millilitre. Multidose vials may require refrigeration after the contents are reconstituted.

Mixing Medications. If two medications are compatible, they can be mixed in one injection if the total dose is within accepted limits. When two or more medications are mixed, the patient will not have to receive more than one injection at a time. Most nursing units keep charts that list common compatible medications. If you have any uncertainty about medication compatibilities, consult a pharmacist.

Mixing Medications From Two Vials. Apply the following principles when mixing medications from two vials:

- Do not contaminate one medication with another.
- Ensure the final dose is accurate.
- Maintain an aseptic technique.

To mix medications from two vials, use only one syringe with a needle or use a syringe with a needleless access device attached (Figure 33-20). Aspirate a volume of air equivalent to the first medication's dose (vial A). Inject the air into vial A, ensuring the needle does not touch the solution. Withdraw the needle and aspirate a volume of air equivalent to the second medication's dose (vial B). Inject the air into vial B. Immediately withdraw the medication from vial B into the syringe, then insert the needle back into vial A, being careful not to push the plunger and expel the medication in the syringe into the vial. Withdraw the desired amount of medication from vial A into the syringe. After withdrawing the necessary amount, withdraw the needle from the syringe. Insert into the syringe a new needle or a needleless access device suitable for injection.

Mixing Medications From One Vial and One Ampule.

When mixing medication from a vial and an ampule, prepare medication from the vial first and then use the same syringe and filter needle to withdraw medication from the ampule. Prepare the medication combination in this order because you do not need to add air to withdraw medication from an ampule.

Insulin Preparation. Insulin is the hormone used to treat diabetes in some patients. Although inhaled insulin has recently been approved for use, insulin is most commonly administered by injection. Because insulin is a protein, if it were taken orally, it would break down and be destroyed in the gastrointestinal tract. Most patients who have diabetes that requires them to take insulin learn to self-administer the injections. In Canada, health care providers usually prescribe insulin in concentrations of 100 units per millilitre of solution, which is called U-100 insulin. Insulin is also commercially available in concentrations of 500 units per millilitre of solution, which is called U-500 insulin. U-500 insulin is five times as strong as U-100 insulin and is used only in rare cases when patients are very resistant to insulin (American Diabetes Association [ADA], 2004).

Use the correct syringe when preparing insulin. For example, use a 100-unit insulin syringe to prepare U-100 insulin. Because no syringe is currently designed to prepare U-500 insulin, medication errors can result when preparing U-500 insulin. The Institute for Safe Medication Practices (2002) recommends that prescribers specify the units and volume (e.g., 150 units, 0.3 mL of U-500 insulin) and that nurses use tuberculin syringes to

► TABLE 33-10 A Comparison of Insulin Preparations

Type of Insulin	Onset	Peak	Duration
Rapid-Acting and Short-Acting (Clear)			
Insulin glulisine (Apidra)	10–15 minutes	1–1.5 hours	3–5 hours
Insulin lispro (Humalog)	10–15 minutes	1–2 hours	3.5–4.75 hours
Insulin aspart (NovoRapid)	10–15 minutes	1–1.5 hours	3–5 hours
Regular insulin (short-acting) insulin* (Humulin-R, Novolin ge Toronto)	30 minutes	2–3 hours	6.5 hours
Intermediate-Acting (Cloudy)			
Isophane insulin suspension (Novolin ge NPH insulin, Humulin N)	3–4 hours	6–12 hours	18–28 hours
Long-Acting (Clear)			
Insulin glargine (Lantus) [†]	90 minutes	Plateau	24 hours
Insulin detemir (Levemir) [†]	90 minutes	“Peakless”	16–24 hours
Premixed insulins (Cloudy)			
Premixed regular insulin—NPH (Humulin 30/70, Novolin ge 30/70, 40/60, 50/50)	30–60 minutes	2–12 hours	18–24 hours
Premixed insulin analogues	30–60 minutes	2–12 hours	18–24 hours
• Biphasic insulin aspart (NovoMix 30) • Insulin lispro/lispro protamine (Humalog Mix25 and Mix50)			

*Regular insulin is the only insulin for intravenous use; when administered intravenously, the onset of action is within 10 to 30 minutes and the peak effect is within 20 to 30 minutes.

[†]Cannot be mixed with other insulins.

Based on Canadian Diabetes Association. (2008). Clinical practice guidelines for the prevention and management of diabetes in Canada. Retrieved from <http://www.diabetes.ca/for-professionals/resources/2008-cpg/>

draw up doses of U-500 insulin. When U-500 insulin is ordered, the following medication calculation must be performed to correctly prepare the insulin:

$$\frac{\text{Dose ordered/Dose on hand} \times \text{Amount on hand}}{\text{Amount to administer}}$$

Example: Mr. Dobbs is ordered 250 units of U-500 insulin.

$$\frac{250 \text{ units ordered}/500 \text{ units of insulin on hand} \times 1 \text{ mL}}{= 0.5 \text{ mL to administer}}$$

Therefore, you need to prepare and administer 0.5 mL of U-500 insulin in a tuberculin syringe.

Insulin is classified by its rate of action: rapid-acting, short-acting, intermediate-acting, or long-acting. Each type has a different onset, peak, and duration of action (Table 33-10). Only regular (short-acting) insulin can be administered intravenously. Orders for insulin injections attempt to imitate the normal pattern of a patient's insulin release from the pancreas. Some insulins come in a stable premixed solution (e.g., “30/70 insulin” comprises 30% regular or short-acting insulin to 70% NPH [neutral protamine Hagedorn] or intermediate-acting insulin). Patients receiving premixed insulins do not need to mix insulins.

A patient with diabetes may require more than one type of insulin. For example, by receiving both a short-acting insulin and an intermediate-acting insulin, a patient receives a more sustained control of blood glucose levels over 24 hours.

Insulin is ordered either by a specific dose at select times or by a sliding scale. A sliding scale dictates a certain dose on the basis of the patient's blood glucose level (Box 33-22). Usually, rapid-acting or short-acting insulins are used for sliding scales.

► BOX 33-22 Example of a Sliding Scale Insulin Order

Give regular insulin subcutaneously:

2 units for glucose 11.1–13.3 mmol/L

4 units for glucose 13.4–13.8 mmol/L

6 units for glucose 13.9–16.7 mmol/L

For glucose greater than 16.8 mmol/L, call physician
